The truth is there are no experts in questions of art, as there are, perhaps, in questions of technique. Expert knowledge presupposes the existence of fixed rules, of a canon. There can be no talk of this in the fine arts. The only element of painting that, at least to a certain point—to the point where the individual conception and, with it, really artistic interest first begins—is under objective rules, is drawing, both from its figure as well as its perspective side. This element can be taught, learnt, and faithfully measured, for nature furnishes the scales. On the other hand, the colour element in painting is subject to absolutely no canon, but at best to subjective feeling, at worst to a fashion of the period. Every artificial colour is a convention; for, as I have argued more particularly in my studies of Sisley and Pissarro, none can truly reproduce the real colours of natural phenomena, and it is wholly a consequence of education and habit, when the polychrome of oil-painting or water-colour more easily excites in us the illusion of colouristic truth than the monochrome of the two-colour or of black and white art. One decade paints in dark, another in bright colours. One school likes powerful, another subdued harmonies of colour. Præ-Raphaelites imitate the tone of old frescoes and faded Gobelins. Puvis de Chavannes took the colour out of his pictures by a transparent white-wash, pale as the moon. Besnard, on the contrary, discharges fireworks, without caring in the least if the mad tumults of colour that he loved are possible or not in nature. Carrière envelops his figures in a dense mist. Cottet has, very recently, brought into fashion the black and dark shadings which go right back from Ribot and Prudhon to Velasquez and Ribera. Who is right? Who is wrong? Here everything is feeling, and consequently subjectivity. Of drawing, one can in all cases say (and by photography irrefutably prove), it is correct, or it is wrong. Colour does not admit of a similar verdict. All that can be said of it is: “I like it,” or “I don’t like it.”

For beauty in art, in the present condition of the perception theory, the physiology and psychology of pleasurable feelings, there is no other standard than subjective feeling. This is dependent on the greater or the less sensitiveness of the nervous system, on its perceptivity of slight qualitative and quantitative differences in the excitation of the senses, and, therefore, on an essentially congenital constitution of the organism. The gift of receiving strong impressions from works of art can be developed by practice, by the frequent and attentive study of works of art of different kinds; but it cannot be attained artificially by any effort or any amount of study.

What, then, mean the expressions expert and layman, when applied to æsthetic verdicts? The classes of society, in which preponderating occupation with intellectual problems, continued through several generations, has refined the nervous system and rendered it more sensitive, produce, as a rule, individuals with a feeling for art. These live in large towns, in the centres of art life, they travel, and visit numerous collections, and thus their feeling for art is developed into a wide understanding of it, that studies works of art from the historical standpoint. These are the real experts, so far as there can be any talk of such in æsthetic questions. But these classes of society, these individuals are only to the very smallest extent painters or professional critics, _i.e._, critics writing for the public. To wish to exclude them, on that account, from the expert class is ludicrous presumption of certain persons who, by their own authority, confer this title on themselves. The educated public—the intellectual _élite_—has not the least reason for allowing their opinion on works of art to be dictated to them by painters who may well be daubers or crack-brained fools, or by

critics who may be ignorant phrase-mongers.

So much for the first question as to the fitness of the so-called layman for criticising works of art.

The second question, as to the changes in public opinion about certain works and their authors, is considerably more complex.

It is not to be gainsaid that such changes have occurred, but they are much rarer than those would like to make us believe who, from instances of pretended later conversions of originally rebellious taste on the part of contemporaries, hope to succeed in proving that the ugly is beautiful and the beautiful is ugly.

The names which were most often cited to prove the incompetency of contemporary judgment on works of art of modern tendency are most unfortunately chosen. Millet, Rousseau, and Corot were looked upon by their contemporaries as smearers and daubers; Manet was laughed to scorn, Böcklin pronounced a fool, his friends advised Hans Thoma to change his name, etc., etc. In order not to go to too great length I will now leave Thoma and Böcklin out of the discussion. But the others! That Rousseau and, especially, Corot passed for smearers and daubers among their contemporaries is simply not true; on the contrary, justice was at once done to them for their technique. Even their most unscrupulous opponents admitted that they were draughtsmen and colourists. What they were reproached with was only the alleged intellectual insignificance of their work. People remained under the influence of classical landscape with ancient buildings or ruins, and a decoration of ideal figures such as Poussin brought into fashion, and Claude Lorrain cultivated. A landscape without nymphs or shepherds in Arcadian dress, without temples or figures of Hermes, seemed empty, insignificant, ignoble. The majority had as yet no taste for the witchery of mood in wood and field. Why, Corot himself was not clear about what was new and determinative in his own art, for in some of his grandest pictures Dryads dance, beneath young-leaved trees immersed in the mists of springtide, the most correct sham-classic square dance. It was only in his last period that he renounced this ancient magic. Rousseau had broken away from tradition more resolutely, and was on that account less esteemed than Corot by contemporaries whose education had been perverted by precedent. But the worst that was said against the two did not go beyond the assertion that they were “vulgar.”

The case of Manet is, of course, different. People have roughly disowned this painter; but it is absolutely false to talk about a change in popular opinion about him. Those who “laughed at” him thirty-five years ago, laugh at him in precisely the same way now. In my study of the Caillebotte room in the Luxembourg Museum I have alluded to the angry protest of Gérôme and Gustave Moreau against admitting the works of Manet and his friends into a State collection. If the laughers are not so numerous, and if their laughter is not so ringing as in the “Olympia” year, it is simply because the man is absolutely done with. Only a few stragglers still talk nonsense about Manet, men who have missed the connection of “the last train,” and some greybeards in their dotage—the barricade warriors of the “Salon”—who fancy they are still breathing the gunpowder smoke of 1863, and will keep up to the day of their death, which cannot be far off, the happy, exultant mood of the beer-evenings at the Café de Madrid. None among the pillars of young and living art recognises Manet as his ancestor. People know now that he was a discovery of Zola’s. The sharp turn in the development of art in the last thirty years of the last century was inaugurated, not by him, but by others. Courbet introduced realism which has nowadays shrunk to nothing. Monet kindled “Free Light,” and that was a very great service which, unfortunately, is also no longer fully acknowledged, for the latest race of Parisian painters again abandons joyful brightness and goes back to the gloomy, oppressive tones of “the ’fifties.” Manet, however, found nothing and invented nothing, and he owes the noise that was, for a period, heard about him only to his relations with a devoted friend, who vindicated his own tendency by that of the painter, and said of him all the good which he thought of himself.

The change in taste from one generation to another is a general law which I proved in the _Neue Freie Presse_ of 9th August 1896, and afterwards developed and established in the Florence _Rivista Moderna_ (No. 3, of 1898, “_Le alternanze del gusto_”). I strongly believe in the prevalence of this law; but if particular cases are followed in detail, it is recognised that many an apparent change in the appreciation of a work or an artist rests on an illusion of the senses.

To return to the subject of Manet. An awful din arose at the first appearance of “Olympia.” Friends and foes waged wild battle with each other. Each panted for the blood of the other. Twenty years later the picture that had been so hotly contested was hung in the State Museum, which roused fresh, but considerably weaker, opposition. Finally, however, no one any longer protested against its presence in the picture-gallery, and now a sophist might assert: “There, you see! The picture which was once laughed at is, thirty years afterwards, acknowledged as a classical work of art.”

Gently! That is by no means proved. The fight has ceased only because it has become objectless. Who nowadays waxes warm against Manet? The man, you know, is dead, not only as a human being, but also as an artist. He no longer troubles any one. He

no longer exercises any bad influence. He no longer even poisons popular taste, for it is sufficient to observe the visitors to the Luxembourg, to see that they pass by the “Olympia” with laughter, and shrugging of the shoulders, or else with astonishment and shakes of the head. If a belated corybant raises a shout of “Hail, Manet!” he is merrily allowed to shout. It is superfluous to shout him down, for nobody listens to him. The truth is that the taste for Manet is not in the least changed. People find the “Olympia” every whit as repulsive nowadays as it was thirty years ago; but they no longer say so with a loud voice and with the veins about their temples swollen, because, generally, people no longer stop before its mouldy ugliness.

If you examine very carefully, you will generally find that the various appraisements of particular works in a new generation do not originate from later generations regarding it differently than did contemporaries, but from their generally no longer viewing it with the same eyes. Let us only bear in mind always that the vast majority of mankind have no feeling of their own for artistic beauty. They act as if they had some feeling only because they know that a feeling for art is pronounced to be a mark of higher culture. We cannot rate too highly the part played in art idiocy by sham culture, pose, and self-deception—or, shall we say, more indulgently, by auto-suggestion? Honest confession of obtuseness to art is hardly found in any but the two poles of humanity—on the extreme summit and at the lowest antipode. A man must be either a rustic lout or an overtopping genius like Prince Bismarck, to confess that he can make nothing of the fine arts. The culture-Philistine never has this courage. He always pretends that he finds luxurious enjoyment in the contemplation of art. This culture-Philistine always repeats what has been said to him; he admires where the Baedeker-star prescribes admiration. And he is, in many cases, not even dishonest. He persuades himself that he feels what he regards it as his duty as an educated man to feel; and he really comes to feel it in the end, thanks to this self-persuasion. All the effects of art depend on suggestion, so far as they are not concerned with the most absolutely primitive and undifferentiated sensual excitations. On one who has a genuine feeling for art the work of art itself conveys the suggestion, which is followed by feelings of pleasure. On the average men, whose blunt nerves take no impression from the work of art itself, the Baedeker-star—the label—exercises this suggestion. If a work of art has once got the reputation of excellence, either because it deserves it, or because it acquired it from a dishonest, busy, bold, and swaggering clique, the next generation of Philistines in art does not test it further, but takes it as something accepted. The clique can then state triumphantly that the work they have puffed is a success. But has it on that account acquired real success?

The number of free, strong men is extremely small, who have the courage, desire, and ability to examine the veracity of traditional labels; but there is a frightful devastation every time that such an idol-destroyer and overthrower of altars breaks into the Temple of Renown, which is guarded by that dragon, the Good Old Way. People are then convinced about the quantity of plaster rubbish which has been smuggled into proximity with real marble and gold-and-ivory work in the semi-darkness of the sanctuary, and has enjoyed for hundreds, perhaps for thousands of years, the same veneration as the wonder-working revelations of genius.

But suppose we conceive in our mind’s eye the extremely rare case in which a real masterpiece was misjudged at first, and, later on, was greeted with acclamations. In this case the question, as a rule, is not of lack of understanding, but of lack of sense of proportion. The contemporary age which blames, and the succeeding age which praises, are both right, _i.e._, they do not praise and blame the same thing, and the divergent appraisement of the work is simply due to the fact that contemporaries like to dwell on the faults and overlook the excellencies, whilst latter generations neglect the faults and regard only the excellencies. The contemporaries were biassed in severity, their successors are biassed in indulgence. Ideal justice is not of this world. But faults remain faults even in the ages that come after, and excellencies, too, were excellencies even in the period of their origin; and it is jugglery and forgery when people interpret the change in appraisement as if a later generation had admired as a merit that which an earlier generation had stigmatised as a fault. Just one example to illustrate these propositions: Millet is said to have passed for “a dauber and smearer.” Now, his contemporaries who blamed him used no such harsh expression. They said only that Millet drew incorrectly and painted carelessly, and those with a real feeling for art notice exactly the same thing to-day, only they say it no longer, unless the question is expressly put to them. On the other hand, his contemporaries, too, noticed his deep moral earnestness, his warm human feeling, the touching simplicity of his style, which we prize so highly in Millet to-day. But they were not inclined to forgive him his defects in execution on account of these intellectual merits, whilst we take his weakness in form into the bargain on account of the feeling it contains. These weaknesses, however, are there to-day precisely as they were thirty years ago, and he who fails to see them is guilty of presumption if he passes a verdict on pictures.

Taking them altogether, the works and artists that were overvalued by contemporaries are far more numerous than those that were underestimated at the beginning. And even in the extremely few cases of the latter category, the injustice of contemporaries did not, as a rule, take the form of violent opposition, but that of indifference. Contemporaries did not gainsay their beauty; but it escaped their attention, because this was claimed by other fashions and styles. No work of plastic art that is nowadays accepted

without dispute was rejected, when it appeared, with such anger as certain products of the “Secession” are at the present day.

That is natural. The conditions of art production were half a century ago absolutely different to what they are now. The artist gave his personality full scope, and sought to please only a few customers of rank, without troubling himself about the people at large. To-day he wants to excite a sensation at any price, and he looks, for this end, not into himself, but about himself. By creating he is not satisfying his impulse to give form and shape, but his hunger for success.

Vain _amour propre_, swaggering, conceited vanity and cunning “pushfulness” are the motives that far too often guide the artist’s brush or chisel. The coarse vulgarity of the means corresponds with the coarse vulgarity of the motives and aims. One must make a sensation, and that is attained most easily by a rowdy rebellion against taste, truth, and healthy human intelligence. If he annoys his contemporaries, the ruthless advertiser finds his account more surely than if he praised them. Only he who startles dares hope to be noticed in our present huge exhibitions with their three thousand numbers. That is why the unscrupulous competitor works with the object of startling, and only with that object. His natural allies are writers who seek by aggressive criticism to satisfy the same hysterical impulse towards sensation as he, and the snobs who hope to justify their claim to be un-Philistine by pretending to discover and appreciate hidden beauties, where the thick-headed majority of their fellow-men observe and condemn only unblushing outrages on the sense of beauty.

The necessity for creating a sensation has arisen only in our times of over-production in all fields of intellectual creation, and of frightfully murderous competition for success. In the earlier days of art it played hardly any part at all. On this account it is fallacious to try to deduce from the, after all, extremely rare romances of works, originally misjudged but afterwards recognised, in the past, an argument in favour of certain creations of the present day, which a large proportion of educated men rejects, not because they do not understand, them, but because they understand them only too well.

Let men only have the quiet courage not to allow themselves to be put out of countenance; they will carry their point even before posterity.

XVII

MY OWN OPINION

There is hardly anything which I hate so cordially as opportunistic criticism, which, in respect of phenomena in art-production presented in a noisy and pretentious way, affecting to signify modernity and progress, does not honestly take a side, but with the cunning foresight of the bat in the fable attempts to come to an understanding with both the opposing armies, of the birds and of the mice. Criticism that openly wears the uniform of a pronounced movement in art can be put up with. The enemy of the movement fights the criticism and the movement at the same time. It shares all the fates of its banner; it is in the danger, and it may be in the victory. If the movement for which it carries weapons succumbs, it gets the worst of it too, and experiences the treatment accorded to the vanquished. It has to lay down its weapons of criticism, falls into contempt, and has no longer the possibility of devastating art life, of perplexing artists, and oppressing those who enjoy art. Insufferable, on the other hand, are the clever, the unprejudiced, the eclectics, the smooth civil sneerers who praise, yet with faintness, who blame, yet with a saving clause, who carry in their lips such well-known and rather good phrases as: “Certainly, there is some exaggeration here, but the peculiar style is not to be misjudged”: “It is certainly no finished creation, but the work, nevertheless, contains some promise”: “This is not exactly a work, you know, which one could recommend for imitation, yet there is much to be learnt from it”: “It is the new wine in Goethe’s _Faust_ that is acting so absurdly, but still perhaps it will yield a good vintage.” These people who talk so sweetly are those who really poison the springs of public taste. Thanks to them, movements which ought to stand without the pale of the law enjoy a sort of equal justification, as it were, of the æsthetic, historico-artistic copyright. Their mask of benevolence, justice, and toleration gains them the confidence of the irresolute, who, left to their own feeling, would recognise, at once, in certain works, either a gross impropriety of the shameless sort, or an indubitable manifestation of insanity, yet through the cheap phrases of opportunistic critics, become doubtful of themselves and say: “If such sober-minded scholars as this and that critic constantly find something to recognise in this stuff, I am perhaps wrong to condemn it at once.”

Moderate feelings are much more widespread than extreme feelings. They are the normal product of the nervous system in civilised men; to the great majority of half-coloured, faded grey men subdued colours only are sympathetic; violent and shrill colours may amuse it; but, in its innermost being, it feels instinctively drawn only to the lukewarm ones. It believes them; and on their information, on their irresponsible recommendation, gives to the most openly rascally art-firms the credit through which alone they

can hold out for a while.

And these critical warpers of justice are not assailable. They always play an imposing part, and are always right. If an objectionable movement lasts—and there are aberrations which have held their ground for at least a generation—then they triumph modestly, for they have been among its first heralds and have “recognised at once the sound kernel in the first strange shell.” If the imbecility is as such patent to all, and disappears amidst the derisive laughter of the intelligent, they triumph again, only somewhat more self-consciously, for they have “not let themselves be dazzled by novelty, and have pointed out its weaknesses, and worked strenuously at its defeat.” Thus every adventure in art life, every campaign in criticism, be its issue what it may, increases their esteem; and the longer they continue their course, which is so mischievous to the community, the more blindly the multitude yields to their leadership, and the greater devastation they are guilty of through their dishonourable exercise of their office of guardians in matters of art.

I well know how this opportunism in criticism arises. It is the result of the co-operation of the basest and most despicable intellectual qualities. I find its causes in the dull feeling for the beautiful which renders weak and indistinct all reactions from artistic influences, and suffers neither delight nor irritation to arise: in the cowardly fear of man and pitiful adulation, which aims at injuring no one and only thinks of keeping a retreat open for itself; finally in common vanity, which prefers to please a crowd of gaping boobies rather than the select few, and the flattering, though so cheap, reputation of being “very intellectual,” to the responsibility of crude performance of duty. The favourite word by which the opportunistic critics compound with every artistic confidence trick is “development.” If the clairvoyant monitor utters the cry of “decay and degeneracy,” the opportunists reply, “buds of a new and splendid bloom.” They love to appeal to the history of art. That is right. When the Masolinos and Masaccios sprang up, the last pupils of Gaddi and Orcagna whimpered, “Now there is an end of painting.” But what was at an end was Byzantine art filled by Cimabue and Giotto with some fresh life, and what began was the ever glorious _Cinquecento_. And much nearer to us: when Delacroix emancipated himself from the colour rules of David’s pupils, and broke out into a downright exultation of red and blue and purple; when Corot, Rousseau, and Dupré set homely nature viewed with lyric eyes in the place of Poussin’s classic landscape degenerated into dial painting; then earnest voices likewise accused the innovators of digging the grave of art, and yet we know nowadays that Delacroix and Corot were by no means the wild anarchists which the Academicians held them to be, and that an uninterrupted line of development extends from David and Prudhon through Géricault to Delacroix, and from Nicholas Poussin and Claude Lorrain through Joseph Vernet, and even through Watteau to Corot—a line which was unnoticed by contemporaries, yet one which we now see clearly. It is the dodge of an unscrupulous attorney to quote these examples when treating of the art of a Puvis de Chavannes, an Aman-Jean, the Præ-Raphaelites, _pointillistes_, _vermicellistes_, and _pipists_. There are sure marks of recognition by which the authorised can be distinguished from the unauthorised, the true from the false, development from retrogression, and buds from gall-nuts. A movement which, indeed, resolutely diverges from the taste dominant at a given time, though striving to approach nature, need not, but may, have a future; and he who does not suffer from stiffness in the joints will not, as a matter of course and on principle, refuse to follow it with benevolent curiosity. If, however, the new movement departs from nature, one may confidently say “it leads to nothing.” If an independent method which strives after personal expression reveals itself in a revolutionary effort—however peculiarly, nay, perversely, it might impress—the intelligent man will not condemn, but wait to see if something living comes from the attempt. If the practised eye, however, recognises, in the peculiarity, either a cunning imitation or a cold-blooded, intentional oddity, then one may confidently pronounce the death sentence, for it contains in itself no germs whatever of development. The only two eternal sources of art are, and will be, feeling for nature and personality. Fidelity to nature and honesty produce living creations. Unnaturalness and affectation are marks of decay. He who ever holds fast to these simple dicta will hardly ever run the risk of mistaking a Will-o’-the-Wisp for a lighthouse, or what is morally, if not practically, a more serious error, of treading under foot an insignificant chrysalis with the living and beautiful butterfly it enshrines.

Even of the manifestations of insanity of crack-brained painters, of the hoaxes of tricky strugglers for success, and the whims of childishly immature and childishly careless people living from hand to mouth, who have sprung up in the last two or three decades, the good man’s insinuating word of the “sound kernel,” of the “tendencies, capable of development, to a new blossoming of art,” has been spoken by the opportunistic of critics. Well, time has now given the answer to these verdicts, at any rate in regard to some of the movements for which those prophets so benevolently predicted a glorious future. Fifteen or twenty years ago we saw in the Paris Salon, beside the expressionless fabrications of the usual daubing artisans—the “Mother’s Joys,” the “Young Lady at her Toilet,” the “Oyster with Lemons,” which constitute the stock in trade of all exhibitions of pictures—only two formulæ appear in hundreds of repetitions: the vulgarly realistic, after the style, let us say—to mention a particular name—of Bastien Lepage, that pupil of Cabanel who had degenerated into an apostle of Courbet; and the pseudo-idealistic, after the model of Puvis de Chavannes. Workmen with brutalised countenances and greasy blouses, and unearthly figures in antiquated landscapes of chalky

paleness, disputed the visitor's attention. A concreteness which did not spare us a single finger-nail in mourning, struggled for supremacy with a careless vagueness which styled itself "Abstraction" or "Synthesis" and produced only questionably schematic types. Whole walls exhibited unbroken rows of pictures which reminded us of the spectral ballet of the dead nuns in "Robert the Devil." Then we came to rooms where an unmixed company of rag-pickers, and night-men exercising their calling, of huzzies on the night-prowl, dung-carting stable-helps, and rapscallions at loggerheads, were quite at home. One of these movements, _i.e._, painting in faint colours, has hardly a representative left; the other—the art of vulgarity, meanness, and ugliness—only a dwindling few.

Here, then, we have two movements, to which "the intellectuals" have promised a future. One of them is as dead as a door-nail and buried, the other dying. He who did not let himself be cheated, or want to cheat others, could predict this outcome with certainty. Debased realism was a misunderstanding of the impulse towards truth displayed by the Manet School. This School held itself bound in conscience to record minutely even the unessential and the ugly accessories. Their limited imitators sought only that which was ugly and unessential in the world of phenomena. They thereby wandered far from the eternal aim of art—to excite an emotion by a work of art; for the mere imitation of a sight either actually indifferent or frankly repulsive can never excite an emotion. It was, therefore, easy to recognise that this tendency could not be lasting. The pseudo-idealism of Puvis de Chavannes showed the other infallible mark of morbidity, viz., impersonality and dishonesty. He tried, by an artificial bleaching of colours and a semi-transparent white-wash, to produce the effect of old and faded frescoes, in which their age of several hundred years is an element of æsthetic effect, by reason of the dim depictment of what is remote, dead and gone, and unknown; by reason of the longing they awake for what has for ever passed away and will never appear again. It was imitation; it was an attempt to deceive. It was not the honest revelation of personality, but its disguise in a strange, historical costume. That had no future, and it could not last.

What justified the primitive naturalism of the pioneers, the convinced fervent service of truth, this survives victoriously every change in fashion, and, in fact, is developing strongly further. True naturalism, which grows enthusiastic for the poetry of unpretentious sights, and was the logical development of Rousseau's return to nature, and of Greuze's village stories inspired by that return (the "Village Bride," the "Father's Curse," the "Son's Punishment," etc.), has held its ground. On the other hand, loathsome painting, which is naturalism run mad, has been finally conquered, and the spectral painting of Puvis is about to follow it into oblivion.

These much-extolled tendencies have, then, no future in them. They were not buds which were to develop into blossom and fruit. They were wild suckers in which a generation of artists fruitlessly squandered its best strength, and which are now withered and blown away by the wind.

And that, too, will be the lot of other aberrations which have not yet quite run their riotous course. That may be predicted with quiet confidence, without any being taught by the future of another.

A great philosophical doctrine is deducible from these facts. All development—including that of art, which is a part of nature and a part of human nature, and obeys the common laws of nature—all development is constant, and will be diverted from its logical course by no power. Its great procession always goes through a main street, and sudden turnings aside branch off only into blind alleys. Extreme forms have no stability; they remain individual monstrosities without issue. The strenuous life is always making efforts back towards the typical constitution of the species. In art this law may be found deplorable up to a certain point; for it is inimical to strong individualities, even to honest and justifiable ones, and favourable to the indifferent average, whilst in art the absolutely untypical individualities are full of charm. But, as things are, it is the iron law of development which no living thing can escape.

It is not easy to oppose successfully the opportunistic criticism which always professes to see, even in the maddest and silliest things, at any rate, "germs of artistic development"; but it is, nevertheless, a duty of subjective morality to do so. My verdict on many notabilities of fashion stands in sharp contrast to that which one generally hears and reads about them nowadays. He who does not suffer from the delusion of greatness, or a morbid distemper of contradiction, feels a position of this kind painfully. I have earnestly and conscientiously tried whether my adversaries were justified in demanding that I, as an individual, should submit to their huge majority. Well, I cannot concede this right to them. In dozens of instances, I have too closely observed how the unanimity of contemporary opinion about an artist arises. It is enough for an artist to invent a whim and obstinately cling to it, without letting himself be put out by indifference, vexation, or scorn. Very soon some ass of a critic will come and explain this whim as an inspiration of genius. This he will do out of vanity, affectation of originality, or an itch for sensation. He will do it to give the impression that he is of more brilliant intellect than the common herd, and that he alone can appreciate a beauty which the

Philistines stupidly pass by. If the humbug of a critic has some skill in coining phrases, a little perseverance, and a fairly sonorous pulpit, he will infallibly, in course of time, collect a congregation around him; for it is easy to gain adherents to a chapel which one designates as a place of worship for the intellectual _élite_, men of fine feelings, and those gifted with understanding. Provided that this sham lasts only a few years, it must needs triumph over all opposition. A young generation grows up which takes it for granted. No one puts to the test what has come into his possession, but takes it as a matter of course. It attains iron permanence. What was a paradox yesterday has attained the rights of dogma to-day by mere lapse of time. Busy pens now vie in outbidding each other in the elegance and wittiness of the phrases with which they express the prescribed admiration for the great man. If an independent person steps forward, and shows the worthlessness of the puffed up celebrity, the devotees of the little chapel, which has grown into a great church, feel an honest indignation against the heretic. “How does this man dare to doubt, when we, who are certainly better and cleverer than he, piously believe.” That is the history of every religion: when it is organised it becomes intolerant and endeavours to assert itself by means of violence. But, to the honour of mankind, there are, nevertheless, always independent spirits who will not let themselves be intimidated, and on whom authority does not impose. They test the dogma, and kick it away if it is not firmly based. The stake has not protected religion from these independent critics; still less can the Corybants of art-reporting guard a fashionable idol from them.

The right of criticising the views even of the most overwhelming majority must be maintained. A final proof in disputed questions regarding æsthetics is, I admit, not to be supplied. All artistic influence rests on suggestion. The work of art, itself and, originally, exercises the suggestion on a minority endowed with delicate sensibilities. On the great majority an opinion of others, delivered with firmness does so. The great majority of people admire one who is praised because it is suggested to them by his trumpeters that it is their duty to admire him. As a matter of fact, they feel the admiration, without being conscious that not the work of art has inspired them with it, but the enthusiastic gossip which they have read and heard about it. These people refuse to believe me when I tell them that they are admiring something which is an aberration. The prior suggestion prevents them from tolerating a fresh suggestion from me. No one, however, can contest this so far as he is quite certain only of his own feelings. In art, effect is an infallible criterion, even if of only subjective value. If a man feels definitely as regards certain pictures that they are valueless and unmeaning, he has a right to express it as strongly and honestly as he feels it, even if millions declare that they discover all kinds of loveliness and depth of meaning in them. One will perhaps fail to convince a single creature, and will, as likely as not, long remain a preacher in the wilderness. But perhaps not for ever. The inventors of a fashionable _culte_, whom their selfishness obliges to stand up for their own work, will not remain in arms for ever and live. Those who worship after them have not the same strong, effective grounds, the originator’s vanity, for defending that _culte_ desperately. The snobs who thronged to it because it was the singularity and they were the exceptions, necessarily abandon it as it becomes commonplace and they find themselves in a vulgar majority. Then the uninfluenced art-conscience again faces the work; it becomes susceptible to the warning of him who was, up to then, “the one voice crying in the wilderness,” and in a short time all lips murmur: “That was indeed a swindle.”

PREFACE

This little book is intended not for the collector or the connoisseur, but merely for those who require an introduction to a field of art hitherto little explored but which will well repay further study.

For fuller information on the subject many sources are available, but a word of caution is necessary. A bibliography of works on Japanese art would be misleading rather than useful, for much of what has been written regarding it is, as criticism, quite valueless.

On Japanese painting the most important, indeed the only sound work, is contained in a series of articles contributed by Mr Arthur Morrison to _The Monthly Review_, 1902-3. The writings of Mr E. F. Strange deal fully and adequately with Colour Printing; Captain Brinkley is a good authority on Keramics, and Mr Josiah Conder on Landscape Gardening and Flower Arrangement.

The Transactions of the Japan Society contain many interesting and well-illustrated articles on Japanese minor arts, and the charm of Japanese life is nowhere reflected more pleasantly than in the writings of Sir Edwin Arnold and Mr Lafcadio Hearn.

To the custodians of public and the owners of private collections I am indebted for many courtesies, and especially to Mr M. Tomkinson, Franche Hall, Kidderminster, for permission to reproduce several of the illustrations in the sumptuous catalogue of his collection.

Lid of Suzuri-bako or Writing-case 124 A Group of Inro 130 A Group of Inro, by Korin 134

FLOWER ARRANGEMENT --

A Flower Composition 148

TAILPIECES --

Equestrian Figures from the Mangwa of Hokusai; Fans from Korin Hiakuzu; and Crests.

CHAPTER I

INTRODUCTORY

In coming to the study of Japanese art we must remember that we are entering a strange world, where life and language, and even modes of thought, run on other lines than ours.

When Japan, only fifty years ago, was thrown open to the Western nations, in our ignorance and folly we were at first inclined to treat the Japanese as a barbaric people. But never was there a greater mistake. For the truth is that their civilisation is not only older than ours but in some respects has advanced much further than we have ever attained. In an æsthetic sense the people of Japan are cultured to a degree far beyond our Western standards; their arts are full of beauties which are too subtle, too refined, for our comprehension.

Here, in the most civilised of all Western nations, one is dubbed a visionary and a dreamer if he hopes to see the day when the pleasures of art shall be the solace of the poor as well as the luxury of the rich. But this happy state has existed in Japan for ages. One of the chief characteristics of the people is their love for beauty both in nature and in art. On the public highways are notices indicating to the wayfarer the points from which the most beautiful prospects may be obtained. The artisan mother in the city carries

her babe out into the public parks at the festival of the cherry blossom, that its infant mind may be permeated by the beauty and fragrance of the flowers.

And, loving beauty, they can also express it, for to learn to write in Japan is in itself a course of training in drawing. In art the European requires that everything should be stated with the utmost fulness of a tedious realism before he can grasp its meaning, but to the more cultured Japanese a mere hint or slight suggestion is sufficient. The leading characteristic of Japanese art is, perhaps, that it leaves so much unsaid. For the Philistine, who bulks so largely in the West, and has to be considered and propitiated at every turn, seems to be quite unknown in Japan. What wonder, then, that, with such a public, their art should be somewhat above our heads.

Doubtless the canons of European art differ widely from those of the Far East, but these things are not essentials. All art is based on convention, in the terms of which its meaning is expressed. If we would understand Japanese art we must accept its conventions; we must learn the language of their art and see things with their eyes.

It is the fault of too many critics of Japanese art that they fail to approach it in this sympathetic attitude, and by such it is quite misunderstood. The mystic and beautiful Buddhist figures are tried by rules of anatomy, and the dreamlike Chinese landscapes by the laws of perspective. The materialist weighs the spiritual in the balance and finds it wanting.

But we seem to be improving in these matters; perhaps we are becoming more humble. Of late years some of our leading artists are beginning to acquire the qualities which Japanese art has shown so long. Who shall say that the work of such an one as Whistler, in its sensitive feeling for balance, in its grace of line, in the unerring instinct which marks its spacing, and in the delicate harmony of its colour, is not essentially Japanese in style? Whether these qualities were knowingly borrowed from the Japanese, or whether the artist evolved them from his own inner consciousness, matters little. The important fact is that the qualities which mark the work of one of the greatest of our modern painters, and distinguish it from that of the vast body of his contemporaries, are just the qualities which for centuries have marked the art of Japan. But we know that Whistler was an enthusiastic admirer of Japanese art, and, doubtless, he would have been the first to acknowledge his debt.

With the younger school Japanese influence has been all-powerful. One might safely say that, but for the Japanese colour print, there would have been no modern poster school, working so daringly in bold outline and broad, flat tints; and recent black and white work is equally indebted to the Japanese woodcuts, with their beautiful, flowing line and dexterous use of solid masses of black.

[Illustration: WILD DUCKS By KORIN (_From a Woodcut in the Korin Hiakuzu_)]

The difference of mental attitude is not the only reason for the wide divergence in methods and ideals of Japanese art from that to which we are accustomed. There are other physical and material causes of great importance which have helped to decide its course. The basis of all pictorial and applied art is architectural, and here we find one starting-point of difference between the styles of the East and the West. The frequency of earthquakes in Japan has rendered impossible the erection of buildings of the stately proportions and massive grandeur of other climes. The old Buddhist temples, which are the chief buildings, cannot vie in importance with those of India or China.

In the Japanese house the walls are but paper screens, the whole weight of the roof being supported by the four corner posts, which, in their turn, are not sunk in the ground but stand on four large stones. This lightness of construction has to a great extent dictated the course taken by the arts of Japan. The Japanese picture, instead of being enclosed in a massive frame, is placed on a light mount of silk brocade, and when not in use is rolled up as we roll a map. And the field of applied art is similarly restricted. The temples contain most of the larger and more important works; there is no place for such in the house. The household furniture is reduced to a minimum. A few mats to sit on, for the Japanese use no chairs; one or two paper screens dividing the house into separate chambers at will; a charcoal brazier; a few cooking utensils and articles of pottery; some lacquered vessels, fans, mirrors, and other ornaments; articles of dress, weapons, and a few personal belongings, form the whole field which is open to the craftsman.

So in Japan we have no rooms crowded with a profusion of heavy ornament. Reticence is the keynote; but what ornament there is must be of exquisite quality.

Before dealing in detail with the different branches of Japanese art it will be well to glance for a little at the history of the nation, in the light of which knowledge we shall better understand the social system under which these arts arose and the mental qualities

which they embody.

The civilisation of Japan was the slow growth of many centuries. For more than two thousand years, if we may believe the ancient records, the Mikado and his forefathers have been absolute rulers of Japan, the present dynasty stretching back in unbroken line to the Emperor Jimmu, who flourished about 600 B.C. But, as written history did not exist till some centuries after the beginning of the Christian era, the records of those early days are of a more or less legendary character, as one might surmise from the fact that the Emperor Jimmu was reported to be the grandson of the Sun Goddess herself.

The origin of the Japanese race is shrouded in mystery. Little is known of them except that, somewhere between two and three thousand years ago, they invaded Japan, and drove out the Ainos, who still survive in the island of Yezo. A Mongolian race, no one can say positively whether the invaders came from China or Korea, from the Malay peninsula or Siam, or whether, indeed, they were an offshoot from the wild Huns against whom China raised the Great Wall. One thing tending to show that they were not a branch of the Chinese race is that, even at that early date, China was the abode of an advanced civilisation; while the Japanese were certainly little removed from barbarism, and, indeed, hardly more civilised than the Ainos whom they displaced.

But the Japanese character has always been receptive, and just as their new civilisation is borrowed from Europe, so for the foundations of the old they are indebted to China. When they first came into contact with influences from the mainland it is hard to tell. It is said that the use of Chinese characters was introduced as early as 157 B.C., and the early records give a full account of an invasion of Korea by the Empress Jingo about 200 A.D. After this victorious expedition many captives are said to have been brought back, who laid the foundations of Chinese learning and culture.

The real civilising of Japan, however, began with the coming of the Buddhist priests from Korea in the middle of the sixth century. Buddhism became the chief religion of the country, largely absorbing, though it never quite superseded, the collection of myths and superstitions known as Shintoism. For Shintoism was hardly a religion in the usual sense of the term. As a Japanese writer admits, it had no moral code; but, he adds naively: “Morals were invented by the Chinese because they were immoral people; whereas in Japan there was no necessity for a system of morals, as everyone acted rightly if he only consulted his own heart.”

The chief centres of the new culture which spread over the land were the great Buddhist monasteries. Just as our own mediæval cathedrals and monasteries were the nurseries of the arts, so in Japan arose a race of artist priests. Their work at first applied solely to religious purposes, but afterwards widened out till, along with the sacred, there existed also a secular school. For three or four hundred years under these benign and mellowing influences the country grew and prospered. The quiet and peaceful times from the eighth to the tenth century especially marked a period of great literary activity, several of the most famous poets of Japan, whose writings still live in old tradition, flourishing during this period.

As time went on, however, the horizon became overcast, and from the twelfth to the end of the sixteenth centuries Japanese history is one long record of strife and civil war. The Mikado became more and more only the nominal ruler; the real power lay in the hands of the warrior nobles.

In the twelfth century arose the terrible struggle between the two rivals, the Taira and Minamoto families, each supporting its own candidate for the throne--a war which gave to legend and story one of its chief heroes--Yoshitsuné, the Bayard of Japan.

A hundred years later Japan, for the only time in her history, had to repel a foreign invader, a huge Tartar armada threatening her shores; but, as in the case of England, the elements fought for the islanders. A terrific storm played havoc with the Tartar fleet, and of all the invading forces it is said that only three men escaped alive, and were sent home to tell the tale.

Then in the fourteenth century the bitter wars of the Ashikaga period once more bathed the country in blood.

Those long years of war set their stamp on the nation, hardened its fibre, and brought out its sterner virtues. A military class--the Samurai--arose, and these trained warriors were maintained by the local Daimios, or princes, to whom they owed feudal obedience. Bushido, the way of the warrior, a stern but lofty creed of valour and devotion to duty, became the real moral code of the nation. For the annals of Japanese knighthood are full of tales of dauntless heroism--tales still told in every cottage in Japan, and retold a hundred times in Japanese art.

In those warlike days there was little place for the gentler arts of peace. But the Buddhist temples still stood--quiet sanctuaries where, undisturbed by the turmoil and strife around them, the gentle, priestly philosophers pursued the even tenor of their way, and kept the lamp of art burning bright and clear. In the outer world the military arts alone flourished, and the swordmaker was the king

of craftsmen.

In the fifteenth century, however, during a period of peace, a second wave of Chinese influence gave a new impetus to art. The Court of the retired Shogun Yoshimasa was a circle of artists and learned men, culture once more reached a high level, and one of the most brilliant periods of Japanese art began.

The sixteenth century saw a gradual consolidation of the empire. The Mikado for long had been little more than the nominal ruler, the chief power lying in the hands of the Shogun, who controlled the whole executive of the state; but the local Daimios gave little more than a mere formal submission to the central authority--each was practically absolute king in his own province. In 1603 Iyeyasu, the first of the Tokugawa Shoguns, for in his family the office became hereditary, came into power. A man of great ability, he set himself to complete the work of subjugation which his predecessors Nobunaga and Hideyoshi had begun, and finally reduced the turbulent nobles to the state of vassals, owing feudal obedience to the Mikado. Under his wise rule the country settled down to a prolonged period of peace, unbroken for two hundred and fifty years, in which art and industry developed greatly.

The Tokugawa period, 1603-1867, especially in its earlier stages, is pre-eminently the period of the minor arts, which then reached a perfection which has not been attained before or since. The force of the nation formerly expended on war was turned into these more peaceful channels. The Daimios of the various provinces carefully fostered the local arts, specimens of which were sent yearly to the Shogun and the Mikado, and a keen rivalry existed between the different districts.

[Illustration: FUKUROKUJIU AND CRANE By KORIN (_From a Woodcut in the Korin Hiakuzu_)]

Often the local lord would establish a kiln on his private estate, where articles of pottery and porcelain were manufactured solely for his own use. In the shelter of his castle, too, the artist in metal or in lacquer worked peacefully, freed from all sordid cares. Time was no object to him, the final result everything. He had to consult no demands of popular taste, his work was always the best he could produce, and often years of labour went to the making of one perfect piece.

As time went on, however, gradually the work lost its first freshness and originality. It became richer and more elaborate but tamer and less vigorous, and by the beginning of the nineteenth century only echoed faintly its former glories. For the burden of feudalism was pressing on the country with more and more weight. The military classes, their employment gone, gradually sank into luxury and indolence; the only sign of life was the gradual rise of a more democratic feeling among the people. The later schools of painting were more or less of the nature of a revolt from the traditions of the older styles, and the art of colour printing saw the rise of a school of democratic artists.

The soil was already prepared, some change was inevitable, and the change came when the country was thrown open to the nations of the West, feudalism finally abolished, and a democratic government established in its place.

But contact with Western ideas and Western methods seemed to give the deathblow to Japanese art. In painting, the European standards have played havoc with the charming and beautiful conventions of old Japan. Aniline dyes have spoilt the soft harmonies of the colour prints. In metal, in carving, and in lacquer the new work is vastly inferior to the old. What the European market clamoured for was not quality but cheapness, and so, adaptive as ever, the Japanese turn out by the hundred superficial and mechanical imitations of the beautiful old work. Modern commercial methods have little to do with art, and in this case seemed at once to turn the artist into a trader.

Japan is now a modern nation, Western in its civilisation, in its methods, and seemingly in its ideals--destined to become a great industrial state. Perhaps, as she has done so often before, she may absorb the new influences, and without loss of individuality follow out her own course. Perhaps, phœnix-like, from the ashes of the old, new arts as brilliant may arise. But, again, some say that art belongs only to the more youthful stages of the world, and that in these days of science never again can the artist be more than a mere survival of an earlier age--one who still keeps green within him the youth which in others has long since withered and died.

[Illustration: Rider on Horseback]

CHAPTER II

PAINTING

In a general survey of the arts of Japan it will be best to begin with the art of painting. In a land of paradoxes there is this paradox regarding Japanese art, that while their pictorial art is the most decorative of all pictorial arts, yet their decorative art is the most pictorial of all decorative arts. For the Japanese decorative artist rarely or never uses ornament merely as ornament; it almost invariably represents something more than mere beauty of line, mass, or colour; there is usually some pictorial motive attached. The lacquerer, for instance, rarely uses purely conventional forms, but flowers, birds, figures, even landscapes, make up his schemes of decoration. It follows, then, that the decorative arts of Japan are dominated by, and indeed are based upon, its pictorial art, and, therefore, the necessary preliminary to their consideration is a study of the art of painting.

The European's introduction to the study of Japanese art is apt to be rather misleading, for in all probability the first specimens which come under his notice are the colour prints and paintings of the naturalistic and decorative schools of the last century. His first shock of surprise overcome, for both the medium and the style of presentment are new and strange, he speedily discovers in them real beauties. Harmonies of line and colour, finer and more subtle than any we have to show, arouse his enthusiasm, and he thinks that he has penetrated the mysteries of Japanese art, and that all its treasures lie before him. Even were it so the boon would be no small one; but, as a matter of fact, he merely stands upon the threshold. The real glories of Japanese painting are the works of hundreds of years ago. As well could one judge of the glories of English literature from the ephemeral periodicals of the day as of the painting of old Japan from the products of the more materialistic schools of recent years. To know English literature one must read the classics; to realise its full glory we must go back to Spenser, Shakespeare, and Milton. And so with Japanese art, we must go back to the works of the old masters--to Cho Densu with his amazing power, to Sesshiu with his wonderful dream landscapes--ere we realise its grandeur. Then we feel that, beautiful pieces of decoration though the modern works are, here we breathe a purer and a finer air; we are in another world, a nobler and a greater one. The finest landscapes in the world are those painted by the old Chinese and Japanese artists; monochromes, slight and shadowy as morning mist, but breathing the very poetry of nature.

[Illustration: ARHAT AND LION From a Kakemono by CHO DENSU (_British Museum_)]

The art of painting was borrowed by Japan from China, the first teachers being the Buddhist priests who crossed over from Korea in the sixth century. This origin, and also the nature of the materials used in the art, stamped it at the outset with qualities which have ever since distinguished it. The ordinary instrument for writing in China and Japan was the brush, dipped in Indian ink, and to form the native characters was in itself an exercise in drawing. Caligraphy, indeed, as penmanship in the old days of mediæval Europe, was reckoned as one of the fine arts; or rather, from the Chinese point of view, painting was reckoned one of the branches of caligraphy. This caligraphic basis is the root of most of the conventions of Chinese and Japanese painting, and in the quality of the brush work are to be discovered many of its beauties. For by means of line alone, not a pen line, thin and hard, but the supple, swelling line of the brush, the artist not only renders the outlines and shapes of things but suggests modelling, chiaroscuro, even the different planes of distance, in a manner indefinable in its subtlety. Colour, except in the later and more naturalistic schools, is used in flat tints only. This absence of chiaroscuro is often quoted as a defect of Japanese art; but if all that can be said has been expressed by line why add light and shade? One has only to study the work of one of their masters in the use of the brush, such an one as Motonobu, of the Kano school, to understand not only how unnecessary it would be but how impossible. We would as soon wish to see filled in one of the exquisite outlines of Flaxman. It is like setting a beautiful poem to music: you may exchange one melody for another, but both cannot exist together. And we must remember that all use of line is a convention, for line does not exist in nature, and Japanese art, after all, only differs in this respect from European art in having used this convention with greater freedom and more consummate mastery.

The simplicity of the means at the artist's disposal--a brush or two, Indian ink, a few liquid colours, and a sheet of paper or silk--tended to produce directness and simplicity of effect, and this tendency was increased by another influence. The Buddhist priests, then as now, were of a type of mind essentially idealistic. Their religion taught them to regard the spiritual essence of things as the great fact and the outward and visible world as merely a temporary and changing phase, and so in their art, for they were the first painters, they aimed not at a literal transcription of nature but at an expression of its inner significance. And this training has always affected the attitude of Japanese art. Directness, reticence, and restraint are its main characteristics. To present the essential quality of a scene, not its mere outward appearance, and that with the least possible obtrusion of the material, was its object.

Even in later days, in their more naturalistic studies, the Japanese artist never dreamt of drawing direct from nature as we do. His system, the system by which children still learn to draw in Japan, was to look steadily at the object to be depicted until it was learned by heart and could be reproduced at will.

In painting the artist seats himself on the floor, the sheet of silk or paper before him. For a while he gazes abstractedly, till the whole picture is clear to his mental vision. Then with the first touch the central point of interest--the eye of a bird, say--is indicated. Swiftly and surely, with a full brush, the rest of the subject is filled in. There is no niggling, no retouching, for the delicate, absorbent surface of the silk will not stand repeated workings. Each stroke is placed on the picture direct as it is to remain, and, though the result may be a masterpiece, the work, in many cases, is that of a few minutes. The technique of the brush has, indeed, been carried to a degree of perfection by the Japanese artist otherwise unheard of. He fills it, or it may be in the case of a large brush each part of it, with just as little or as much ink or colour as he desires, carefully arranges the hairs in a certain way, for the preparation and loading of the brush is often as important as the actual brush stroke, and then with one single sweep obtains the whole effect he requires. Many are the wonderful tales of the feats which the old masters could perform with one stroke of the brush.

A word may here be said as to the forms which pictorial art assumes in Japan.

The first and most common form is the kakemono, or hanging picture, formed of a sheet of silk or paper, richly mounted on brocade of various colours. It is furnished with rollers like a map, and is rolled up tightly when not in use. This is bad for the surface of the painting, cracks being inevitable if much body colour has been used, but it is a great protection against the fires which are so frequent in the light wooden houses of Japan; for, as there is a considerable space between the picture and the top of the mount, several layers of brocade and tough mounting paper are thus tightly wound round the painting.

[Illustration: AN IMPRESSIONIST LANDSCAPE From a Makimono by SESSON (_British Museum_)]

The two ribbons, which so pleasantly break the monotony of the upper part of the mount, are not merely ornamental. When the moving screens forming the side of the house have been moved back for coolness, and the kakemono hangs in the open air, the _futai_, as these ribbons are called, flap in the breeze, and prevent birds from alighting on the upper roller.

The makimono, or horizontal roll, is largely used for historical scenes or for landscape sketches, the series, many feet long, often forming one continuous composition. It is not hung up but laid on the floor, and unrolled and examined bit by bit, as we would look at the pictures in a book. Originally the kakemono was exclusively used for sacred, and the makimono for secular, subjects, but this distinction has long since ceased to exist.

A third form, gaku, is stretched on a frame, after the manner of our pictures, but is little used.

Screens, both folding and sliding, were greatly used for the longer and more important pictures. Sometimes a screen of five or six panels will be so treated that while the whole forms one composition yet each panel taken separately also forms a complete picture. Books, each page stiff and opening on a hinge like a miniature screen, are also used. Lastly, mural decorations on wood or plaster, and the dainty little paintings on fans, complete the forms of pictorial art most in vogue in Japan.

Some time about the end of the fifth or the beginning of the sixth century the Buddhist priests crossed over from Korea, and formed the first Japanese school of painting, devoted almost entirely to the sacred subjects which were used to decorate the Buddhist shrines. Very beautiful and dignified are many of these old Butsugwa paintings, recalling in their rich, full colour and their lavish use of gold the illuminations and early paintings of our European monasteries. In most cases they are unsigned, the holy man deeming it unfitting that objects intended for such sacred uses should be contaminated by earthly associations. The British Museum collection contains several fine specimens, which, though faded and sadly blackened with incense fumes, show these early works worthy to compare, for elevation of tone and religious fervour, with the finest works of Christian art.

For many years this Buddhist school of painting continued, its traditions lasting without a break until the fifteenth century. And here at the outset it will be well to call attention to a difficulty which arises in any attempt to give a brief and clear account of the history of painting in Japan. The matter is complicated by the fact that, though the different schools of painting are evolved one from the other, the later did not supersede the earlier form, but usually both continued to exist contemporaneously. Many artists painted in the styles of more than one school, the manner often being decided by the choice of subject, and latterly it was part of the training of Japanese artists to go through all the schools.

Then, again, some of the greatest masters, especially those of the last two centuries, formed their styles by adopting and combining what appeared to them best in each school. To follow out logically the growth of the various schools, and at the same time to treat of the different artists in a chronological order, is, therefore, a matter of some difficulty.

The oldest picture in Japan of which there is any authentic record was painted, probably by a Korean priest in the beginning of the seventh century, on the plaster wall of the Buddhist temple Horiuji at Nara, a storehouse filled with treasures of ancient art. For three hundred years little more is known--the names of a few priests and one or two priceless paintings are all that remain; but by the ninth century civilisation had reached an advanced stage, the country was rich and prosperous, and entered into a great literary and artistic epoch. The poets Narihira and Komachi, still ranked among the immortals, were contemporaries of Kosé no Kanaoka, the first great secular painter of Japan, and, if the double evidence of popular legend and the verdict of critics and artists of his own and later days is to be believed, the greatest of all Japanese artists. About a dozen examples, said to be by Kanaoka, exist, but, one by one, the genuineness of each has been questioned by experts. Perhaps the most authentic is the portrait of Shotoku Daishi at the Ninnaji temple in Kioto, which has been reproduced in colours in the _Kokkwa_, the Japanese Government publication. Although nearly all the existing pictures attributed to him are Buddhistic figure pieces, Kanaoka's popular reputation was based on his paintings of secular subjects, portraits, landscapes, and animals. He was especially famous as a painter of horses.

The story goes that in a certain temple hung a painting by Kanaoka of a magnificent black steed. The peasants in the neighbourhood were much annoyed by the ravages of some wild animal, which nightly raided their gardens, eating the herbs and trampling the flowers. At last they lay in wait, and found to their surprise that the intruder was a huge black horse. On their pursuing it disappeared into the temple, but when they followed the building was empty. As they stood below the picture great drops of sweat fell down, and there was Kanaoka's horse all hot and steaming. Then one of them had a happy idea. Seizing a brush he rapidly painted in a rope tethering it to a post, and the gardens were no more invaded by the nocturnal visitor.

The work of the immediate followers of Kanaoka seemed to be chiefly Buddhistic in style, but this may only mean that the only specimens which have survived the ravages of time are those sacred pieces which were safely stored in the temples, and that, like Kanaoka, they were equally at home in secular subjects.

In the tenth century Kasuga no Motomitsu founded the first purely native school, called the Yamato school, which afterwards, under the name of the Tosa school, became the recognised style for the treating of historical subjects.

The eleventh, twelfth, and thirteenth centuries formed a period of great literary and artistic activity. Buddhism was then in the height of its power, and there is no greater period than this in the history of Japanese art, but of these old masters we know little more than the names. In the twelfth century we have Takuma Shoga, Sumiyoshi Keion, and Toba Sojo, the last a marvellous animal painter, but examples of their work are practically unknown out of Japan. In the thirteenth century we have Fujiwara no Nobuzané, of whose Buddhistic work the British Museum has a fine specimen; and a hundred years later Kosé no Korehisa, renowned as the greatest military painter of Japan.

In 1351 was born a truly great artist, Meicho, or Cho Densu, whom some rank as the equal of Kanaoka himself. A Buddhist priest, he was famed for his sanctity, and the bulk of his works are of a religious nature, to which field he did much to bring new life and vigour, for the school had relapsed into the dull repetition of cut-and-dry formulas. But in secular subjects he was equally great. The British Museum is fortunate enough to possess a masterpiece by Cho Densu--a figure of an Arhat seated with a lion at his feet. The whole picture is presented with extraordinary force. The attention is seized and held by the eyes of the figure as they stare fixedly at the lion, which, with head thrown back and gums bared, glares savagely in return. The drawing is superb in its easy power, the colour rich and sombre, its highest note in the bright red of the lion's jaws.

A new influence arose with the Chinese renaissance of the fifteenth century, and we come to the times of the great landscape painters. Nothing could be further removed from the attitude of the modern European landscapist than that of these old Chinese and Japanese masters. Their object was not to depict a scene in a naturalistic manner but to convey its inmost spirit. In speaking of a painter of a later day a Japanese critic writes: "But in his landscape there is less success, as he was so particular about ensuring correctness of forms that they were lacking in high ideas and deep spirit. For a landscape painting is not loved because it is a facsimile of the natural scene but because there is something in it greater than mere accurate representation of natural forms, which appeals to our feelings, but which we cannot express in words." It is this deeper and inner art which the old landscapists give us. In monochrome, or with a few sombre tints added, they suggest the beauty, the repose, and the dignity of nature in a way that, to my mind, no landscape painters have done before or since. One little Chinese landscape especially lingers in my memory, though it was not the original I saw, only one of the delicate collotypes which can only be produced in Japan. It was called "The Evening Bell." On the strip of soft, brown-tinted silk is faintly touched a range of peaks against the sky; nearer is a grove of trees. Mist lies in the hollows and softens the forms, and in the distance, amid the tree-tops, peeps out a temple roof. Nothing could be slighter or yet more complete.

The old Chinese style, so strongly marked in the work of the old painter priests, had gradually fallen into disuse before the more popular Tosa style, when Josetsu, a Chinese painter, settled in Japan early in the fifteenth century. Little is known of Josetsu's own work; but his influence soon began to make itself felt, and he gathered round him a band of pupils. Of these the most famous is Shiubun, a Buddhist priest, still regarded as one of the greatest of Japanese landscape painters. The British Museum contains a very fine painting attributed to him, though expert criticism rather inclines to assign it to a somewhat later period.

[Illustration: A LANDSCAPE IN THE CHINESE STYLE By SESSHIU (_British Museum_)]

Shiubun had two brilliant pupils, Oguri Sotan and No-ami, the first a priest, a fine landscapist, and a wonderful painter of birds and flowers; the second a brilliant and versatile man of the world, courtier, poet, caligraphist, critic, and painter. In the last capacity he was especially renowned for his paintings of tigers. No-ami had a son Gei-ami and a grandson So-ami, both of whom, especially the latter, became famous landscapists of the Chinese school.

But the most famous of all the masters of the Chinese renaissance is Sesshiu, born 1420, died 1506, one of the greatest of all Japanese painters. As a youth he entered a Buddhist temple, but his thoughts were often far away from his religious duties. The story goes that once, as a punishment for some fault, he was tied to a pillar of the temple. With tears for ink, and using his toe as a brush, he sketched some rats on the floor, and as each was completed it sprang up, and began to gnaw through the rope that bound him. On the approach of the chief priest they scampered away; but the good monk was so impressed by the miracle that the youthful artist was henceforth allowed to follow his own bent.

At the age of forty Sesshiu, satisfied that he had learned all he could from the artists of his native country, went to China to study under the masters there, but to his surprise and discouragement he found none there who could teach him more than he already knew. Then said he: "Nature shall be my teacher; I shall go to the woods, the mountains, and the streams and learn from them." So for some time he travelled in China painting and studying nature. His fame soon spread through the land, and the Chinese artists, frankly acknowledging him as their master, came to him for instruction. By the Emperor himself he was commissioned to paint a series of panels on the walls of the palace at Pekin, and on one of these, to mark his Japanese origin, the artist has placed a view of Fujisan.

It is by his landscapes that Sesshiu is best known, and never was the grandeur and the dignity of nature more fully expressed; but his figure subjects, notably the magnificent painting of Jurojin, the god of longevity, reproduced in the _Kokkwa_, and, in the British Museum collection, a wonderful study of Hotei, the god of contentment, frolicking with some children, must be seen before his full scope and great power can be realised. For he was in every sense a great painter; in each department his work is marked by lofty conception, great breadth of treatment, and an absolute certainty and ease of execution. His brushwork is very distinctive, and even by the novice may be recognised at a glance. Strong and vigorous, but angular and jagged like forked lightning, it often seems rude and clumsy when examined closely, but it never so asserts itself when we step back and look at the _picture_, but expresses exactly the effect intended. The British Museum possesses several very fine specimens of Sesshiu's work. Even of the most famous of his pupils--Shiugetsu, Sesson, and Keishoki--space will not permit us to deal. Mention must be made, however, of a makimono by Sesson. It consists of eight views in monochrome roughly dashed off. Nothing could be more sketchy than the treatment or yet more vigorous. It is a veritable _tour de force_ of caligraphic impressionism.

A secondary result of the Chinese renaissance was the foundation of the Kano school, which, based on the broad, caligraphic methods of the Chinese masters, gradually adapted them to their own use, evolving a freer and looser style of handling distinctly Japanese. The founder of the school was Kano Masanobu. When the artist Oguri Sotan died, in 1469, he was engaged in the decoration of the walls of the temple of Kinkakuji at Kioto, and, on Sesshiu's recommendation, Masanobu, then only known as an amateur, was engaged to finish the work.

[Illustration: SHORIKEN CROSSING THE SEA ON HIS SWORD From a Kakemono by MOTONOBU (_British Museum_)]

Masanobu's son Motonobu was even more famous, and to him is due the credit of forcing the new school into public favour. Born in 1477, in his youth he wandered over the country, carrying little but his brushes, painting everything he saw, and paying his way with the results. But those lean years of poverty and study stood him in good stead. Fortune smiled at last, and he became the most popular painter of his day. Goto Yujo, the famous metal worker, adopted his designs for sword ornaments, his painted fans were chosen as ceremonial gifts to the Mikado and Shogun, and, to crown all, Mitsushigé, the head of the exclusive and aristocratic Tosa school, gave him the hand of his daughter in marriage. He died, full of years and honours, in 1559. For landscape, birds, and figure subjects he is equally famous, and as a master of the brush he is unsurpassed. In the work of the Chinese schools the quality of

line, though often striking, is used in a more reticent way, entirely as a means to an end; but in the Kano school the line becomes a thing of beauty and life, almost an end in itself. The astonishing power and sweep of Motonobu's line may be seen to perfection in the Shoriken in the British Museum.

During the sixteenth century the Kano school numbered many famous names. Yeitoku, a grandson of Motonobu, became the favourite painter of the Shogun Hideyoshi. Kaihoku Yusho was noted for his beautiful misty effects; and more famous, perhaps, than either is Kimura Sanraku. Sanraku was at first a page in the service of Hideyoshi, who, discovering his talent, sent him to study under Yeitoku. His work has all the dash and swing of the Kano style, and his colouring is rich and harmonious, while his line is almost worthy to rank with that of Motonobu. Sanraku's adopted son Sansetsu carried on the tradition of the family, though his work has more of the restrained quality of Sesshiu and his followers than the dash of his more immediate predecessors. The British Museum has a beautiful rainy landscape by Sansetsu, slight in treatment--only some dim hills drenched in misty rain, with the suggestion of a bridge and a stream and a fisherman's cottage--but everything, even the cottage roof, looks wet. (See frontispiece.)

In the beginning of the seventeenth century the Kano school took a new lease of life with the advent of the three brothers, grandsons of Yeitoku, Tanyu, Naonobu, and Yasunobu.

Of the three, Tanyu is the most famous, and is recognised as one of the greatest masters of the Kano school. He is distinctly a painter's painter, and delights in what we should call fireworks. Handling his brush with careless ease he makes a smudge, a few blots, and a swirl, and behold a landscape! A very Japanese Whistler; but it marks the difference between the two publics that, while Whistler is with us still "caviare to the general," the Japanese substitute is one of the most popular of all their painters. His two large pictures of Kwannon, however, in the British Museum, stamp him as no mere swaggerer but a great and serious artist. In the private collection of Mr Arthur Morrison are two magnificent sixfold landscape screens, which show him to rank with the first of Japanese landscape painters, and, among other unique examples of his work, a dainty little study of birds and convolvulus, touched with the utmost lightness and delicacy.

[Illustration: KWANNON, THE GODDESS OF MERCY From a Kakemono by TANYU (_British Museum_)]

Naonobu, the second brother, died at an early age, and from this cause, and from the fact that he seemed to spend much of his time in hunting out and destroying his earlier work, his paintings are rarer than Tanyu's. There could hardly be a greater contrast than the work of the two brothers--the first exulting in its strength, and full of a superb recklessness and dash; the second restrained and quiet, though not lacking in force, and full of a soft, liquid quality. Some charming examples of his work are in the British Museum.

The third brother, Yasunobu, was known chiefly for his landscapes, full of delicacy and feeling, and recalling the work of Sesshiu and Sansetsu.

Naonobu's son Tsunenobu, born in 1636, was a worthy successor, and, in the opinion of many, is worthy to be ranked with Tanyu and the other great men of the Kano school.

Then we have one of the most striking personalities among Japanese painters--Hanabusa Itcho, the last of the great Kano painters. A born humorist, his faculty for practical joking was always getting him into trouble. Indeed, on more than one occasion he found himself in prison owing to liberties he had taken in the pictorial representation of those in high authority. But he is no mere caricaturist. His drawings are pictures first and humorous afterwards, and as a colourist he ranks high even in Japan.

Another pupil of Yasunobu was Sotatsu, one of the greatest flower painters of Japan. He also studied under Sumiyoshi Jokei, a Tosa painter, but can hardly be classed with either of these schools.

It must not be supposed, however, that with the coming of the Sesshiu and Kano schools the old Tosa style had been driven out. It continued to exist alongside the newer schools, and many artists changed from one style to the other according to subject. The Tosa school at this time was distinguished by a minuteness of detail, and also by a richness of colour which gradually came to affect the Kano artists, whose work became much brighter in colour as time went on. Sesshiu, Masanobu, and Motonobu worked chiefly in monochrome, using colour sparingly; but Sanraku's work, a hundred years later, is full of fresh, bright tints. A curious convention of the Tosa painters in their historical subjects was to leave out the roof of a house in order to expose the interior to view.

[Illustration: BIRD AND PINE BRANCH From a Kakemono by NAONOBU (_British Museum_)]

We now come to Ogata Korin, one of the most individual of all Japanese artists. Born in 1661, he is said to have studied under Yasunobu, and the influence of Sotatsu seems to appear in his work; but he can be classed with no existing school, striking out an entirely new line for himself. A wonderful draughtsman, Korin possessed in the highest degree the Japanese faculty for spacing and balance. Slight, and often almost bizarre, as his compositions are, one feels that it would be impossible to alter a line. He is more frankly decorative than any of his predecessors, and is even more famous as a lacquerer than a painter. Indeed, often in his painting, especially in the enamel-like quality of his colour effects, one sees the hand of the lacquerer rather than the painter. Japan, perhaps, possesses one or two greater artists, but none more original, or whose work exercises a more subtle fascination. To commemorate the centenary of his death his follower Hoitsu issued several volumes of woodcuts from the master's designs. Slight as these are they are never trivial, nothing is expressed but what is necessary, the non-essentials are absolutely ignored, and the results are masterly in their telling arrangements of black and white.

We must now retrace our steps a little and return to the beginning of the seventeenth century, when Iwasa Matabei founded the style which was known as the Ukioyé, or "pictures of the passing world" school, and which soon became the great popular school of painting. The distinction between the Ukioyé and the older classical schools, however, was not one merely of subject. Many of the earlier men had turned to the scenes of everyday life for their subjects. Toba Sojo, Sanraku, and Itcho, to name but a few, and, on the other hand, the Ukioyé painters, frequently treated of classical subjects. The real difference is one of treatment, not of subject, and the starting-point of variance was the mental attitude of the painter. It was a departure from the subjective attitude of the older men. The Ukioyé and later schools took the standpoint of the poet: "The earth--that is sufficient; I do not want the constellations any nearer"--and their works are frankly decorative or frankly naturalistic. Materialists, in a sense, they turn from the beauties of the ideal world to show us the beauties of the natural world around us. This does not necessarily mean that their treatment was what we term realistic; but, while with the classical schools one looked through the picture, as it were, to the thought beyond, in this case one looks at the picture for the beauty which it presents, and which is inherent in the subject itself. The fact that the rise of the Ukioyé school was more or less a popular revolt against the old classical traditions which had governed the art for a thousand years will help to explain to us why its masters were hardly esteemed as highly by the cultured classes in Japan as, by their undoubtedly fine qualities, they deserved to be. On the other hand, we must admit that they never attain to the power and dignity of the older schools.

[Illustration: FLOWER PANEL By KORIN (_From a Woodcut in the Korin Hiakuzu_)]

The works of Matabei are excessively rare. He was a fine draughtsman, his figures of dancing girls being particularly graceful in line and of quiet, harmonious colouring.

The next great artist of the school was Hishigawa Moronobu, who flourished during the latter part of the seventeenth century. Formerly a designer of embroideries, the inexhaustible fancy with which he adorns the costumes of his figures adds a special charm to his work, and his drawing of the figure is marked by a wonderful lightness and grace. He was the first artist of importance to devote himself to the production of the woodcut prints which afterwards attained such popularity, and during the next two hundred years became a separate branch of art industry.

During the eighteenth century the school obtained many adherents, whom, for lack of space, we can do no more than name. Torii Kiyonobu, the first of the Torii artists, noted for their treatment of theatrical subjects; Miyagawa Choshun, Nishikawa Sukenobu, Okumura Masanobu, Nishimura Shigenaga, and Suzuki Harunobu are but a few. But as most of these painters of the Ukioyé school were more famous as producers of colour prints we shall leave their further consideration to the next chapter.

[Illustration: MONKEYS AND PLUM BLOSSOM From a Kakemono by SOSEN (_British Museum_)]

A great painter of the eighteenth century who did not follow the Ukioyé or older schools, but, like Korin, struck out a line of his own, was Tani Buncho, who was born in 1763 and died in 1841. As a painter of landscapes, figures, birds, and flowers he was equally a master.

Another artist who struck out for himself is Maruyama Okio, 1733-1795, sometimes regarded as the founder of the Shijo or naturalistic school. According to the old critics, "the art of painting may be pursued according to either of two systems: the one in which the spirit of nature is expressed; the other in which its outward forms are copied." Okio broke away from the old traditional method, and instead of endeavouring to interpret Nature endeavoured to so present Nature that she should deliver her own message. His favourite subjects were birds, fish, and flowers, and in their naturalistic treatment are more akin to European work than that of his predecessors, though in grace and elegance they are still essentially Japanese.

In the hands of his followers the Shijo or naturalistic school soon became popular. Even more famous than Okio was Mori Sosen, 1747-1821, now recognised as one of the world's greatest animal painters. He is especially noted for his paintings of monkeys, whose habits he studied for years, often living in the woods for months at a time. He has two styles: one rough and bold, generally on paper; the other on silk, and often of extraordinary delicacy and fineness. That his abilities were not by any means confined to the depicting of monkeys may be seen from his exquisite studies of deer and other animals.

To landscape Mori Ippo applied the principles of the Shijo school, employing a much more naturalistic colouring than had hitherto been the custom, and Hoyen depicted birds, flowers, and insects with charming delicacy and refinement.

In 1749 was born another great independent artist--Ganku, who founded a school of his own, combining with the naturalism of the new something of the suavity and dignity of the older styles.

Though treating of him more fully in the next chapter mention must be made here of the great Hokusai--in Whistler's words, "the greatest pictorial artist since Vandyke." To European ears his name is more familiar than that of any other Japanese artist. As a draughtsman he ranks with the very first, and as a painter his brushwork was bold and free and often masterly, though lacking just the grace and finish of the old Kano masters, and, at its best, his colour is superb. Some of his figure subjects have the grandiose quality of a Velasquez. His versatility was extraordinary, every style of subject coming within the range of his brush.

[Illustration: A PEACOCK From a Kakemono by IPPO (_British Museum_)]

Of nineteenth century painters the greatest is Kikuchi Yosai, the last of the great painters of Japan. In his youth he studied in all the schools, and afterwards made a tour through the country studying the great pictures stored in the various temples. His own style is strongly individual, combining the dignity of the older schools with the realism and rich colouring of the modern. A fine example in the British Museum is his painting of Fukurokujiu, the god of longevity--an old, old man with worn, wrinkled features. It is said to be a portrait of the artist, and was painted in his eighty-fifth year. He had many pupils but no successors; and on his death, in 1878, the only painters worthy of mention are Zeshin, better known as a lacquerer, who died in 1891; and Kawanabé Kiosai, a humorous draughtsman of remarkable dexterity, who died in 1889.

CHAPTER III

COLOUR PRINTING

The art of colour printing, which, as pointed out in the previous chapter, was an offshoot of the Ukioyé school of painting, is one of the most interesting of the minor arts of Japan. It was the colour prints that first aroused the interest of the European in Japanese art, and it is from them that in most cases he still receives his first impressions. And though, indeed, these impressions require largely to be corrected in the light of further knowledge, yet on the whole this is the most natural introduction; for, fantastic though these prints may at first appear to the unaccustomed eye, yet in their frankly decorative feeling they approach more nearly the Western standpoint than the earlier and more ideal schools of Japanese art. In the colour prints, which we may buy for a few shillings, there are obvious beauties of line, of composition, and of colour which cannot fail to appeal to us; however strange or bizarre they may otherwise appear we at once recognise them as charming pieces of decoration.

And though on further acquaintance with the subject of Japanese art we find that those who produced this beautiful work were but the journalists of art, and that the real classics stand on another and higher plane, yet on their own merits we cannot grudge them unstinted praise. They have not the noble elevation of the old schools, they do not climb the misty heights of the ideal, but they realise with exquisite feeling and refinement the beauty of the passing world that lies around them.

And while Japanese paintings, especially of the older schools, are almost unknown except to the connoisseur, and are only to be seen in a few isolated collections, the colour print is more or less familiar to all who take an interest in matters artistic. Hardly a studio but possesses a print or two, and it would be difficult to over-estimate their influence on the work which goes on around them.

But the art of the colour printer has this additional interest for us: it was a truly democratic art, its followers men of the artisan class, its customers the common people. And at a time when the upper classes of society were suffering from a gradual degeneration, when the arts became less and less alive and more and more a repetition of outworn conventions, this growth from below of a school of living art shows that the popular masses were beginning to stir, and that even two hundred years ago the bonds of

feudalism were getting weaker, and the growth of a popular art was only one manifestation of the tendencies which finally overthrew the old system and substituted for it a democratic government.

The colour print artists were, for the most part, ignored by the cultured upper classes. They were men of little or no education. Toyokuni I. was the son of a maker of puppets; Kunisada was at one time the keeper of a ferry-boat; and Hokkei was a fish-hawker before he found his vocation. Then there was another reason for this social boycotting--the subjects of which they treated in their pictures. A large proportion of these were representations of actors in character. Now, in Japan the fondness for the theatre was an overwhelming passion with the common people, but by the nobility and aristocracy the stage was utterly tabooed. No person of good family dared openly to attend a theatrical performance. Actors, therefore, were ranked in the social scale as the lowest of the low--beneath even the humblest artisans. Even the colour print artists, who earned their living by depicting them, would never dream of associating with them on terms of equality.

Then another favourite subject was the delineation of the famous beauties of the Yoshiwara and the tea-houses. It is evident that the nature of the subject in this case also would be sufficient to damn the prints in the eyes of the better classes.

But, with the alien, “where ignorance is bliss, ’tis folly to be wise”; and where the educated Japanese would see vulgarity and coarseness--where, perhaps, such was even intended--we, happily, see only a beautiful decorative effect.

So in Japan the colour print was the picture of the poorer classes. Costing a mere trifle, it occupied in their humble homes the place of the more expensive kakemono.

It is a matter of surprise to the cultured Japanese to find how these despised objects are prized by European collectors; and, valuing them little themselves, they have exported them wholesale, till comparatively few remain in Japan, the bulk of fine prints being now in Europe or America.

Though far surpassing in delicacy and beauty the colour prints of Europe and elsewhere, the Japanese prints are produced by means wonderfully simple, and depend for their fine qualities entirely on the wonderful skill of the craftsman.

The process is as follows:--The drawing is first made by the artist, with brush and Indian ink, on a sheet of thin paper. After being oiled to make it transparent this paper is pasted, face downwards to ensure the necessary reversal, on a block of soft cherry-wood. The engraver now proceeds to outline the picture with a knife. Then with gauge and chisel the superfluous wood is boldly cut away, and the result is a key block in line. From proofs coloured by the artist a further series of blocks are cut, one for each colour used. It may be mentioned here that the cherry-wood blocks are not cut across the grain, as in the case of the boxwood blocks we use for wood engraving, but in a line with the grain.

Then comes the work of a third craftsman, the printer. He mixes his colours for each printing, and applies them carefully to the block with a brush. Then the paper is damped and laid on the block. No press is used, but with a rubber or baren, made of a bunch of twisted fibre in a sheaf of bamboo leaf, the impression is carefully rubbed off. And so each block is used in succession until the picture is complete, accuracy of register being obtained in the most wonderful manner by rough guiding marks cut on the blocks. Sometimes metallic dusts are used in printing, and again a kind of embossing or high relief is obtained by pressure on an uninked block. It is said that this pressure is often applied by using the point of the elbow as a rubber.

The prints were issued by publishers chiefly in Yedo, the engraver and printer being simply workmen in the publisher’s employment. Sometimes the artist, too, was employed entirely by him, living in his house, and occupying a position somewhat equivalent to that of a designer for a commercial firm.

The first Japanese artist to make drawings for the wood engraver was Hishigawa Moronobu (1637-1714). These, however, were not colour prints but merely woodcuts in black and white. He illustrated quite a number of books during the latter half of the seventeenth century.

A further development was the colouring of the prints by hand, which was introduced largely by Torii Kiyonobu (1664-1729), the founder of the long line of Torii artists who devoted themselves almost entirely to theatrical subjects. It is among the immediate successors of Torii Kiyonobu that the art of printing in colours direct from the blocks appears to have arisen--at first only one or two tints being used.

The perfecting of the process is due to Suzuki Harunobu, who, going beyond a few tints on the main objects, filled in the whole picture with colour. And, though the first of the great colour print artists, in many respects his work has never been surpassed. Most

of his prints are small in size, containing only a single figure, exquisitely poised, and characterised by extreme elegance and grace of line. His colour schemes were quiet and refined--grey, a pale red, one or two tints of olive green, being the components of some of his most delicate harmonies. His prints are rare, and his signature has been paid the doubtful compliment of being more extensively forged than that of any of his fellow-artists. His style, however, was more difficult to reproduce. Many of his successors fell under his influence, but even in their most successful efforts they never quite caught his peculiar elegance and charm.

[Illustration: A FIGURE GROUP From a Colour Print by UTAMARO]

Of his contemporaries the most noteworthy was Koriusai. Less delicate and refined than Harunobu, he worked in a bolder style, his drawing being particularly vigorous. His bird studies are very fine; and South Kensington Museum contains some excellent examples of his work--notably one, a clever contrast of a crow and a white heron against a grey-green background.

Reflecting Harunobu more decidedly is Shunsho, who became the master of the great Hokusai. His studies of female figures are particularly graceful and of charming colour, and his prints of theatrical subjects vigorous and striking. He died in 1790, at the age of sixty-seven.

Contemporary with Shunsho was Torii Kiyonaga, an artist who not only did fine work himself but exercised a great influence on the artists who followed him. Working with fuller colour than his predecessors he increased the number of blocks considerably, and his charming drawings of the gorgeously-dressed beauties of the Yoshiwara set the fashion afterwards so largely followed.

We now come to one of the chief of the colour print artists--Kitagawa Utamaro, next to Hokusai the most famous of all. His female studies were something quite new and distinctive, superb in line and composition, the heavy masses of black being used with consummate ease and mastery. There is an exquisite quality in his drawing, too; the features are delineated with the utmost fineness and delicacy. Indeed, to distinguish a forgery from a genuine Utamaro, one has only to examine the drawing of the hands and the face. His colour is delightful, and beautifully subtle--lavender, pink, green, and grey--but always saved from weakness by the dexterous use of the masses of solid black. Besides his female figures we have a few landscapes and flower studies, and a particularly fine little volume of insect drawings. It is related by his father in the preface of this book that, when a child, Utamaro was continually catching and examining insects, till he was afraid that the boy might acquire a habit of killing the harmless creatures. The book, however, is not entirely devoted to harmless insects, one of the drawings being a masterly study of a snake. A touch of mica used in the printing gives it a slimy sheen, and the long, coiling body, every inch of it alive and moving, is a wonderful piece of drawing. To rival it one would require to turn to the work of another Japanese artist--the netsuké carver.

Yeishi, Yeizan, and Kiyomine, who followed immediately after, adopted his style and followed his methods closely; but rich though their effects are, and full of detail, they lack the dignity and simplicity of the earlier workers.

One of the most characteristic of all the great artists, and worthy to rank with Harunobu and Utamaro, is Toyokuni I., born in 1769. His work also was at first affected by the ornate style of Kiyonaga; and among his earlier prints are studies of gorgeously-dressed ladies, a riot of rich colour and elaborate detail, but later he turned his attention to theatrical prints, and evolved the style, distinctively his own, which became afterwards the recognised method of treating such subjects. In his lines the grace and suavity of the earlier masters become hardened to a certain severity, but what was lost in grace was gained in strength. The violent action in some of his prints is an illustration of the forcible manner in which the truth can be conveyed by a judicious exaggeration; and again, in repose, his figures have a dignity which is monumental. This effect is heightened, too, by the reticence and restraint with which he uses colour--full, strong tints, but few, and laid on in broad masses. Breadth of effect was what he aimed at and secured. In Japan he was more popular than any of his contemporaries, Utamaro not excepted; and, whereas their followers were limited to a few immediate successors, he was the founder of a regular school. Of these the best is Kunisada, known as Toyokuni II., whose early work especially was almost worthy to rank with that of his master.

But the greatest master of all the colour print artists, and one who by European critics has been acclaimed as worthy to rank with the great artists of the world, was Hokusai. It is a mark of the power of his personality that, though he lived and died in poverty and obscurity, the facts of his life are recorded with some degree of fulness; while, as a rule, little record is left of his contemporaries but their work. Born in 1760, he was apprenticed at the age of eighteen to Shunsho, but was too original in his methods, and too independent, to remain in that position long. For some years he drifted about, being reduced at one time to hawking red pepper, calendars, and other small wares in the streets of Yedo, but all the time he was getting more and more command over his art.

[Illustration: A FIGURE STUDY From a Colour Print by TOYOKUNI]

In the preface to the “Hundred Views of Fuji” he thus summarises his life: “From the age of six I had a mania for drawing the forms of things. By the time I was fifty I had published an infinity of designs; but all I have produced before the age of seventy is not worth taking into account. At seventy-three I have learned a little about the real structure of nature, of animals, plants, trees, birds, fishes, and insects. In consequence, when I am eighty, I shall have made still more progress. At ninety I shall penetrate the mystery of things; at a hundred I shall certainly have reached a marvellous stage; and when I am a hundred and ten everything I do, be it but a dot or a line, will be alive. I beg those who live as long as I to see if I do not keep my word. Written at the age of seventy-five by me, once Hokusai, to-day Gwakio Rojin, the old man mad about drawing.”

And, indeed, this was no idle boast, for he lived to a great age, and steadily gained power. When finally stricken down the old man’s lively spirit is still unsubdued, and he writes playfully to a friend: “King Yemma [the Japanese Pluto], being very old, is retiring from business, so he has built a pretty country house, and asks me to go and paint a kakemono for him. I am thus obliged to leave, and when I go shall carry my drawings with me. I am going to take a room at the corner of the street, and shall be happy to see you whenever you pass that way.”

To the end his mind was absorbed by his art. On his death-bed he was heard to murmur: “If Heaven could only grant me ten more years.” Then a moment after: “If Heaven had only granted me five more years I should have become a real painter.” He died on the 10th of May 1849, in his ninetieth year.

On his tomb is inscribed this little verse, composed, according to the national custom, during his last hours:

“My soul, turned Will-o’-the-wisp, Can come and go at ease over the summer fields.”

All his life beset with poverty, unhappy in his domestic life, his dauntless spirit sustained him, and his incessant industry never flagged. He lived for the most part with one daughter, an artist also, in a bare room, with little or no furniture beyond his painting materials. When the room became unbearably dirty--and they were not squeamish--they changed to another house. Always poor, dressed like a pauper, ascetic in his mode of life, he had an utter contempt for money. When he received payment for his work the money lay uncounted at his side, and when importuned by a creditor he threw him one of the unopened packets and went back to his work.

In 1817 he published the first volume of the “Mangwa,” a collection of rough sketches, which, in its fifteen volumes, forms a veritable encyclopædia of Japanese life and industries, and is sufficient alone to establish him as one of the great draughtsmen of the world. These sketches were printed from woodblocks in a scheme of black, grey, and light red, and included studies of every kind--street scenes, architecture, birds, beasts, flowers, and insects. The “Hundred Views of Fuji,” similar in style, added still further to his reputation.

But even more striking and distinctive is the great series of colour prints illustrating the landscape of his country--the waterfalls, the bridges, and the “Thirty-Six Views of Fuji,” which are something quite new in Japanese art, not conventional landscapes of the old Chinese style, abstract and ideal scenes, but pictures of certain places, each with its individuality strongly stamped upon it. They are, however, equally far from the Western realistic standpoint, each picture being an audacious decorative arrangement both as regards line and colour. Most daring of all are the waterfalls, superb in their boldness of conception and rich, full colour, but equally fascinating are the quieter harmonies of the “Thirty-Six Views of Fuji.” To study such pictures is to be lifted out of the commonplace view of things and to look at nature through the temperament and with the eyes of a poet.

But, while so highly esteemed by European connoisseurs, Hokusai is by no means so highly thought of in Japan. And this is not entirely due to the fact that he was a man of the people, a painter of the vulgar and the commonplace. Though it is hardly possible for us to overrate the magnitude of his genius, still, the more we learn of the great painters of the older schools the more we see the reason of the Japanese verdict, for even we would hesitate to place his work alongside that of Cho Densu, of Sesshiu, and of the great Kano masters. The fact is that no man, however great, can afford to do as Hokusai did--to set aside altogether the accumulated benefits of centuries of experience and work absolutely fresh from the beginning. The greatness of his achievement shows the power of his personality, but the greatest results of all are built on the foundations of others. And in spite of its amazing originality and its force we must recognise that in Hokusai’s style there is a lack of the dignified reticence and grace--the culture, in fact--of the best work of the classic schools.

[Illustration: ONE OF THE THIRTY-SIX VIEWS OF FUJI From a Colour Print by HOKUSAI]

But the distinction lies even deeper. His outlook, keen and marvellously accurate to catch any passing phase, has not the deep seriousness of the older masters. He was a modern of the moderns--materialistic, humorous, somewhat flippant--while they were mystics, striving to pierce through the veil and discover the truths lying beyond. Each represents the spirit of his time, and, though the comparison is interesting and needful, it is due more in justice to the older men than to Hokusai, whose reputation, it is safe to say, will in Europe mount higher and higher, while the qualities of the old classic painters will appeal to but a few kindred spirits.

One other colour printer of the first rank remains--Hiroshigé I., worthy to rank with Harunobu, Utamaro, Toyokuni, and Hokusai. His landscape prints are particularly charming in their delicate renderings of effects of atmosphere and light, and no one could portray better the peaceful effects of quiet evening light.

But the art which culminated in the work of these great men entered now into a period of decline. The latest artists brought nothing that was new; and, charming though much of their work was, it merely repeated, with continually lessening effect, what had been said before.

With the opening of the country to European influence came the final degradation--the introduction of violent aniline dyes to take the place of the old soft Japanese tints.

Since 1880 a slight revival of the art has taken place, but it has, as yet, produced nothing to rival the productions of even fifty years ago.

[Illustration: A LANDSCAPE From a Colour Print by HIROSHIGÉ]

CHAPTER IV

SCULPTURE AND CARVING

Like the sister art of painting, the art of sculpture arose in Japan with the coming of the Buddhist priests from Korea in the sixth century. But though both existed together in the great Buddhist monasteries the latter seemed for the first few hundred years to entirely eclipse the former, for the first great products of Buddhist art in Japan were seen in the figures carved in wood or cast in bronze which adorned the shrines of the temples.

Time, too, has dealt less severely with these relics, or rather, less perishable in their nature, they have been better able to survive the dangers that so often swept away the frailer kakemonos of the painter, and in many of the old temples are preserved the works of these early sculptors. Such statues were rarely or never in stone, but either of wood--which material always seems as plastic as clay in the hands of the Japanese craftsman--or cast in bronze. Why this should have been it is difficult to say. Perhaps the lack of a suitable stone at hand, and the difficulty of transporting large and heavy blocks long distances in a rough and hilly country, had something to do with the matter. In any case, wood and bronze were at first entirely used for the work. Some centuries later a fine grey clay, found at Nara, mixed with vegetable fibre, like the bricks of Egypt, and, like them, hardened without baking, came into use. Another interesting method of working was the covering over with thin lacquer, mixed with powdered bark, a model made of coarse cloth stiffened with glue. Works in both these last styles were frequently gilded or painted.

Arising in India, Buddhist art spread northward with the spread of the creed through China to Korea, and as it went farther north its characteristics were largely altered and moulded by the different types of the northern Buddhists. The Hindu sensitiveness gave place to a Chinese solidity, which, again, was mellowed and softened by the gentler influences of Korea.

The early Buddhist altar-pieces of Japan are marked by a sweet and dignified serenity. Unlike the great Greek sculptures, they do not represent the ideal of the natural human form, but rather endeavour to express in terms of the human form an abstract or spiritual beauty. Their figures are personifications of abstract qualities--Reason, Pity, Charity, Fortitude, Beauty, Divine Love, for the northern Buddhist doctrine was a gentle one; the world was not a hopeless dream, as in the Hindu form, but a storehouse of forms to be idealised.

The temple of Horiuji at Nara, the first Buddhist temple built in Japan, is one of the richest of all in art treasures, and contains many fine examples of the old work. One of the earliest known specimens there is a life-sized seated figure of Kwannon, said to be the work of Prince Shotoku himself, and, in any case, dating from about the end of the sixth century. The figure is nude from the waist upwards, and is modelled with great severity of style, so that the anatomical forms are almost lost; but this, with the simplicity of the drapery, only concentrates the attention on the serene dignity of the expression, and adds to the power and impressiveness of the

statue.

During the seventh century there arose at Nara a school of bronze casters, who produced a number of beautiful altar-pieces, more than a hundred of which still exist. They are of small size, varying from six inches to three feet in height, and in delicacy of modelling and elegance of style they far surpass any of the Indian, Chinese, or Korean work. The triumph of the school is seen in a little group of three at Horiuji: a seated Buddha with two standing figures, backed by a richly-wrought folding screen.

It is a beautiful piece of work, the lines graceful and flowing, the modelling subtle and of exquisite finish. Perhaps the finest part of all is the openwork halo, pierced with a floral design, behind the head of the central figure. In its own way this group, executed about 680 A.D., is one of the gems of Japanese art.

Towards the end of the seventh century a wave of Greek feeling, which had slowly spread from India and had produced what was known as the Greco-Buddhist art, reached Japan, and its influence is seen in a certain ampler sense of human dignity and proportion absent in the earlier works. In 695 A.D. an attempt was made to cast three large bronze figures of about twelve feet high, but it was a failure. In 715 A.D., however, Giogi, who ranks among Japan's greatest sculptors, successfully cast an altarpiece for the temple of Yakushiji, Nara, of even greater dimensions--a trinity of a seated Buddha and two standing figures. In the opinion of many this work represents the culmination of the art of bronze casting in Japan. For largeness of conception, easy grace and elegance of pose, richness and beauty of finish, it has never been surpassed.

[Illustration: COLOSSAL BRONZE IMAGE OF A BODHISATWA (_South Kensington Museum_)]

But a still more astonishing development was yet to come in the colossal bronzes, which exceed in size any other pieces of casting the world has seen. The largest of all, a seated Buddha, is at Nara, and, no less than fifty-three feet in height, is the greatest bronze statue that has ever been cast. A figure of great dignity, it has, however, suffered much by the lapse of years. The head was damaged by an earthquake in 855 A.D., and later by a fire, and was finally replaced by another in the sixteenth century. Much finer as a work of art, though slightly smaller, being forty-nine feet seven inches in height, is the Daibutsu, or Great Buddha, at Kamakura, which is considerably later in date, the best judges placing it at 1252. The seated figure, with hands folded in contemplation, is of almost oppressive dignity and power. The modelling is simple and severe, the drapery hangs in large ample folds, and the face bears an expression of profound and majestic calm. In the history of art we have met such an expression before; there is something akin to it in the strange, inscrutable smile of the Sphinx. But the calm of the Buddha has a deeper and more spiritual quality: it is the calm of perfect knowledge; it speaks of the conquest of human passions and a spiritual peace elevated far above all earthly things.

The statue was originally surrounded by a building fifty yards square, the roof supported by sixty-three massive pillars; but this shelter was swept away by a tidal wave in 1369, and again in 1494. Since the latter date it has not been rebuilt, though the stone foundations may still be seen. In the rather irreverent phrase of the Japanese, the Daibutsu has become a "wet god."

The process of casting these colossal bronzes is not known in detail. In all probability a full-sized model was first built up, and from it the mould made in several pieces. The Kamakura Daibutsu is formed of sheets of bronze, each cast separately, then brazed together, and finished on the outside with the chisel.

With the decline of this old Buddhist work in bronze appeared another phase of the sculptor's art, which continued to a much later date, and exhibited a different side of the national character. I refer to the grotesque figures of gods or demons which are so characteristic of early Japanese carving. These vary in size from a few inches to between twenty and thirty feet in height, and are chiefly executed in wood, several pieces being joined together in the larger works.

The most famous exponent of the school was Unkei, who lived at the end of the twelfth, and beginning of the thirteenth century. At the gateway of the temple of To-Dai-ji at Nara stood a pair of Nio, or Temple Guardians--huge figures of sinister aspect and terrific power, hewn out of wood--the one by Unkei, the other by Kwaikei, his contemporary. It is said that after Unkei's death the king of the nether world objected that, whereas the sculptor had many times endeavoured to depict him, he had never succeeded in doing him justice. Accordingly, Unkei was sent back to the earth that, having seen the god himself, he might carve his portrait faithfully.

Though on a small scale, only standing two and a half feet high, a pair of little wooden demons by Koben, the third son of Unkei, exhibit the same grotesqueness, combined with an almost terrible power. The masterly representation of the straining muscles shows clearly that the Japanese artist could model the human figure realistically when he pleased, and that when he conventionalised he did so knowingly, and for a given purpose, as has been the custom of the decorative artist from time

immemorial.

The third phase, which marks the early sculptures, is the series of portrait statues, chiefly carved in wood, and it is curious to know that most of these extremely realistic studies were executed during the highly idealistic Buddhist period. The statues of two saints, for instance, Asanga and Vasubandhu, in Kofukuji, which are said to date from the eighth century, are absolutely realistic in style. The drapery certainly is treated in a broad and simple manner, but the face and expression is obviously a portrait, a study of an individual. Many of these portraits exist, dating chiefly from the eighth to about the thirteenth century, and are all strong and characteristic presentments of actual men--speaking likenesses.

[Illustration: PORTRAIT OF SENNO RIKIU, CARVED IN WOOD AND LACQUERED (_British Museum_)]

Towards the end of the thirteenth century the sculptor's art gradually fell into disuse, the traditions of the craft only surviving in the beautiful carving which adorned the temple buildings, but which was looked on not as the work of an artist but merely as that of a carpenter.

The legitimate successor of the old sculptors appeared some hundreds of years later, and not as the maker of colossal images and life-sized portraits, but as the netsuké carver, the greatest master of the art of _multum in parvo_ that the world has seen. In the narrow field of a cubic inch or so the sculptor, for he is no less, combines a largeness of conception with a breadth and vigour of execution which are absolutely astonishing. But there is between the old Buddhist sculptor and the netsuké and okimono carver the same difference which divides the painter of the old classic schools from the more modern exponent of the Ukioyé-Riu--the change from the ideal point of view to the material. The art of the netsuké carver, often bold and vigorous, sometimes elaborately finished, is always frankly realistic.

The netsuké (pronounced netské) is a toggle or button varying in size, but often little larger than a marble. The Japanese gentleman in native costume has no pockets other than his wide sleeves, and so his pipe and tobacco pouch, his inro or medicine-box, and other small objects, are carried slung by a cord to his girdle, like a chatelaine. At the end of the cord was the netsuké, which prevented the objects from slipping to the ground.

It is said that the use of the netsuké dates from the fifteenth century, but the great majority have been made within the last two hundred years. In the opinion of the expert the finest specimens date from the eighteenth and early nineteenth centuries. As the nineteenth century advanced a loss of breadth in the treatment is observable, with a greater elaboration of detail, and this tendency caused the gradual degeneration of the art, until it became little more than a wonderful exhibition of perfect manual skill, lacking the life which breathed in the older work.

The netsuké is made of various materials, of which the two chief are wood and ivory, and is pierced with one or more holes for the passage of the cord. In the eyes of the connoisseur the wooden specimens are generally the most valuable; and justly so, for not only are the Japanese most masterly artists in wood, but the material lends itself to a freer and bolder style of work than the harder and unsympathetic ivory, retaining the slightest impression of the artist's individuality. Between the two there is much the same difference as between the free and spontaneous clay sketch of the sculptor, recording the very print of his fingers, and the coldly severe and more pretentious marble.

Still, it must be admitted that even in ivory the Japanese carver attained in a wonderful degree the qualities of freshness and ease which we are accustomed to look for only in more ductile materials.

The shape and size of the netsuké is regulated by the purpose for which it is intended. It must be large enough not to slip through the girdle, and we usually find that they range from about the size of a walnut to nearly three times that size. Any excrescences or projections would, of course, be liable to snap off, and so, especially in the older specimens, the outline is generally rounded, and without sharp angles. The holes through which the cord passes are often ingeniously made to form part of the design. The fact that many netsukés were also used as seals, and also that so many early examples are of triangular form, so as to stand firmly on their base, is looked on by some authorities as evidence that the netsuké was evolved from the seal.

Often the wood used was coloured, lacquered, and gilt. Sometimes wood and ivory were combined, often ivory and metal, but almost every material was used on occasion. Porcelain netsukés were not uncommon, and gold, silver, jet, coral, and enamel were all applied to the ornamentation of the netsuké.

The Kagami-buta were buttons of metal with a shank at the back. This was enclosed in a circular hollow dish of ivory or wood, which had a hole in the back through which the cord attached to the shank passed. These examples are often very beautiful, the combination of the metal centre, often chased and adorned with gold and silver, with the plain outer ring of ivory being very pleasing in effect.

The Manju netsuké, a round, flattened disc, so called from its resemblance to a Manju, or rice cake, is another well-known form.

[Illustration: A GROUP OF NETSUKÉS (_British Museum_)]

As to subject, the whole field of Japanese mythology, history, and literature is recorded in their netsuké. Perhaps the finest of all are the miniature representations of the masks used in the No dance--sometimes beautiful, sometimes comical, often grotesque, but always artistic. Then we have the beautifully finished carvings of insects; snakes twisted in lifelike coils; a goose with its bill caught in a closed clam shell, and vainly flapping its wings; fishes, tortoises, mice--all varieties of animal life: it is a veritable illustrated natural history. Then in lifelike groups we have the whole world of legendary folklore laid before us. The Tongue-cut sparrow, Motomoro the peach child, and many other old fairy tales, are here retold; while men and women in all the occupations of their trades and callings give an epitome of contemporary Japanese life.

The names of the famous netsuké carvers are too numerous to record here. One of the most celebrated was Shuzan, who lived early in the eighteenth century, a volume of whose designs was published in 1781.

Of late years, since the use of the netsuké has begun to die out, the carver has turned his attention to okimono--small pieces not pierced for the cord, and intended merely as cabinet ornaments. Many of these little ivories are exquisitely beautiful. European work, even of the best, looks weak and poor beside them; and even the best Chinese carving, though perhaps equally dexterous in manipulation, seems dull and mechanical contrasted with their never-failing fertility of imagination.

[Illustration: Rider on Horseback]

CHAPTER V

METAL WORK

We have already treated, with some fulness, of the beautiful bronze statues which adorned the old Buddhist temples; but though his highest achievement, these represent only a small part of the work of the Japanese bronze caster. The old temple bells, the incense burners, the great temple lanterns, all were of exquisite workmanship. And the art was also applied to domestic uses, the ordinary cooking utensils, the more ornamental vases, and the dainty bronze mirrors being but a few of its products.

One of the finest and oldest bells is at the temple of To-Dai-ji at Nara. Cast in 732 A.D., it stands 13 feet 6 inches high, the diameter across the rim is 9 feet 1 inch, while the weight of metal is over forty tons.

The method of ringing such a bell is different from that to which we are accustomed. Instead of a loose tongue hung inside, a heavy swing beam is mounted outside the bell, which it strikes on the rim. The vibrations of each stroke are allowed to die away ere the next is struck, and the great waves of sound go pealing for miles over the quiet countryside.

The casting of a temple bell was made the occasion of a great religious festival. A large kiln was built, worshippers attended from all the surrounding country, women casting their ornaments into the melting-pot. The priests announced with a loud voice the successful accomplishment of each stage of the work, and the concluding operations took place amid scenes of great rejoicings.

At To-Dai-ji is also a very fine specimen of a temple lantern, ornamented with beautiful openwork panels; while at the temple of Kofukuji, Nara, is a masterly piece of bronze in the shape of a musical instrument, a sort of gong, called the Kwagen-Kei, surrounded by four twining dragons--a most fantastic but vigorous piece of modelling.

The mirrors of polished bronze are said to have been first cast in the reign of Keiko, about 100 A.D. They are of two kinds--the first fitted with a handle, or with a stand of metal or carved wood; and the second much smaller, often not more than four inches in diameter, with a hole at the back through which a cord passed. The face was burnished, and the back beautifully wrought in designs of great delicacy.

[Illustration: TWO BOWLS OF CAST BRONZE (18TH CENTURY) (_South Kensington Museum_)]

The method of casting employed in these and similar articles, which is still characteristic of Japanese work, was as follows:--An exact model of the object, with the ornamentation complete as in the finished article, was made in wax. A slip was then prepared with very fine sand, clay, and water, and the model carefully coated with the mixture, special care being taken to run it into all the hollow places, so that a complete skin covered the wax at every part. When the first coat dried another was added, and another and another, a slightly thicker paste being used for each successive coat. A coarser and stronger mixture was used for the outer layers, till the model was encased in a hard, solid crust. Vent holes were then drilled and the wax melted out. After being carefully heated the moulds were ready to receive the molten metal, which was then poured in. When the casting was cold the moulds were broken off and the metal exposed to view. This system not only ensured individuality in the work, a fresh mould being made for each piece, but allowed of a depth of modelling and under-cutting which would have been impossible had the mould been in pieces to be drawn apart and afterwards used again.

The metal work of Japan may be conveniently grouped in three classes. First, the early work characterised by extreme elegance, ornament being used sparingly, though with great taste and often marvellous vigour. Then comes a middle period, dating from the coming of the Tokugawa dynasty at the end of the sixteenth century, when a class of work highly ornamented and rich in detail came into vogue. And, lastly, we have the more modern naturalistic school, wonderful in technique, but lacking the inspiration of the older styles, and beside it appearing dull and commonplace.

South Kensington Museum is particularly rich in Japanese metal work, especially bronzes, of all these styles. There are several fine temple lanterns, notably one pair, standing about eight feet high, of very elegant design, and ornamented with great reticence and taste. A smaller pair, evidently later in date, contain some wonderful casting, but in their more ornate quality lack the dignity of the first pair.

A piece much esteemed by some critics is the large Koro, or incense burner, of quite modern work, cast in 1878--a life-sized study of peacocks, doves, and sparrows. It is certainly a wonderful piece of realism. The poses are natural, the texture of the feathers is imitated in the unyielding metal with marvellous fidelity, single plumes standing out in full relief; but, placed beside the best old work, the whole thing seems trivial and even vulgar. The birds are lifelike to just this extent: if they were only coloured we should think they were stuffed specimens. But from the true artist we get more than this camera-like reproduction of nature; he can also give us the spirit. Turn from this case to the Miochin eagle beside it. As a piece of realism it is worthy to compare with the other, but how much more it conveys. There is a marvellous poise about the bird, a vigour and sweep of line that makes it live and breathe the intense ferocity of its nature. It is alive, while the other merely irritates by its close resemblance to life. Of iron, partly cast and partly made up of hammered plates, it is the work of Miochin Muneharu, a member of the famous Miochin family of armourers, and dates from the sixteenth century.

The smaller pieces in the collection--the vases, trays, bowls, and candlesticks--are also well worthy of study, and illustrate the same tendency--the older work charming by its stately simplicity, and sometimes also by its vigorous treatment of the grotesque; the modern apt to become a mass of exquisitely executed decorations of a highly naturalistic but rather trivial nature.

But in the early years of Japan the implements of war chiefly occupied the attention of the metal worker, and during the bitter civil wars that devastated the country the swordsmith and the armourer became persons of great importance.

The famous family of Miochin has been associated with the making of arms and armour as far back as records extend. An authentic member of the family, Masuda Munemori, wrought helmets and armour in 75 A.D.; and, further back still, there is the legendary founder of the line, who is said to be the grandson of the god Takara himself, who taught him the art of working in metals. From the twelfth to the eighteenth centuries they held the position of armourers to the Court.

[Illustration: THE MIOCHIN EAGLE Cast and Hammered Iron, 16th century (_South Kensington Museum_)]

The armour of the Miochins was formed of thin iron plates, very light, but wonderfully strong. One specimen, a helmet of the sixteenth century, though 12 inches in length, 10 in width, and 8 in height, only weighs 2 lbs. 2 oz. The usual shape of helmet was a domelike headpiece, strengthened with ridges of iron plates, while flaps formed of a number of narrow plates hung at the sides, and covered the back of the neck. From the centre, just above the forehead, rose two curious curved horns, called tsunomoto, and between them was worn the crest of the warrior. In a famous suit of Miochin armour of the twelfth century the helmet has a dragon worked in repoussé coiling round it, the head, with open mouth, glaring from between the tsunomoto, while the tail forms the spike on the top. Although wrought in so hard a metal as iron the dragon’s head stands up in relief at least an inch from the background. Similar work in repoussé adorns the breastplate and armpieces.

But much of the finest work of the Japanese metal worker is found in the two-handed swords, which were the chief weapon of the soldiers, and which, in feudal times, became the distinctive mark of the Samurai, the aristocratic military class. The Japanese blades are unsurpassed by the most famous swords of Damascus, India, and Persia, and the craft of the swordsmith was looked on as the most honourable of all handicrafts. Men of aristocratic birth often took up its duties, and the famous swordmakers had the highest titles conferred upon them. The name of the greatest of them all--Masamuné--passed into the language as a term signifying supreme excellence, for a Masamuné blade was unequalled, and would sever a floating hair carried against its edge by the gentle current of a stream, or cleave through a solid bar of iron.

The sword, indeed, was the centre of the old military life of Japan. To know its history, its etiquette, was part of the education of all Samurai youths, and it was a grand moment for them when, at the age of fifteen, they entered on man's estate and girded on the coveted weapon.

A fine sword was handed down from father to son as an heirloom; it was their most cherished possession, and especially in the more peaceful times which followed the establishment of the Tokugawa dynasty it was enriched with the finest work that art could produce.

The forging of a sword was conducted with almost the solemnity attending a religious rite. The katanya, or swordsmith, fasted for days before, and when all was prepared he went to the temple and prayed for a blessing on his work. In the forge was hung a consecrated rope of straw and clippings of paper to drive away evil spirits; and, having first propitiated the five elements--fire, water, wood, metal, and earth--the smith donned the ceremonial robes of a Court noble, and, binding back the wide sleeves, was ready to take hammer in hand.

First a strip of steel is welded to a bar of iron, which serves as a handle; other strips are placed upon it, and it is wrought into a bar of the required dimensions. Carefully coated with a paste of clay and ashes, and never touched with the naked hand, this bar is heated in the charcoal furnace, notched in the middle with a chisel, doubled over, and then beaten out to its former size and shape. This folding process is repeated fifteen times, then four such bars are welded together, and the doubling and welding repeated five more times, so that if each bar consisted first of all of four flakes this has now been increased to 16,777,216 layers of metal. Many different textures are obtained by flattening the bar in different manners, some giving the appearance of a grain as in wood. The preparatory welding being finished, the blade is then drawn out to its full length, shaped, and roughly ground.

But the most critical part of the process, the tempering of the steel, is now to come. And the peculiar combination required--an extremely hard edge, with the rest of the blade soft and tough--the Japanese swordsmith, unlike others, produces in one operation instead of two. The blade is coated with a mixture of fine clay and powdered charcoal. This covering is then scraped away along the edge, leaving exposed a strip of metal about a quarter of an inch wide. Raised in the furnace to the required heat, the blade glowing dull red while the edge is white hot, the sword is then plunged into a bath of water at a certain temperature, and the operation is finished.

The process of tempering was always conducted by the forger himself, no one else being allowed to enter the precincts of the forge, so jealously were his professional secrets guarded. It is said that a famous swordsmith paid for this knowledge by the loss of his hand. He had learned all but the heat of the tempering bath, and this vital secret his master refused to impart to him, so at the critical moment he burst into the forge and plunged his hand into the water. The furious master struck off his hand with one blow of the unfinished sword, but the apprentice had learned his secret.

The old smiths used to sing while tempering a blade, and the spirit of the music was said to enter into the metal. Masamuné chanted a refrain: "Tenku, taihei, taihei"--"Peace be on earth, peace"--and his swords never failed their owner, but always bore him to victory. But the blades of his saturnine pupil Muramasa always brought trouble with them. Their owners were ever in quarrels, and, once unsheathed, the sword was never satisfied without blood, so that it could not even be handled with safety. The reason for this was that, as he tempered the blades, Muramasa sang grimly: "Tenku tairan, tenku tairan"--"Trouble in the world, trouble in the world."

After tempering, the blade was slowly ground on a series of whetstones, getting finer and finer, finishing with a careful polishing with stone-powder, and oil.

A volume might be written on the decoration of the sword. The tsuba or guard, the handle of the ko-katana or little knife, carried in the side of the scabbard; the fuchi and kashira, or mounts of the handle, especially were marked by the most exquisite

ornamentation.

In his knowledge of the properties of different metals and their alloys, and in his combinations of these for one general effect, the Japanese metal worker is unique. Many of the alloys used by him were quite unknown to us, and were chosen chiefly for their colours. For the metal workers' designs were in reality colour studies, and in metal he possessed a palette of really astonishing variety. For black he had shakudo, a rich, deep tint, flashing in some lights a violet blue. Oxidised iron gave a very dark brown, almost black, and also a rich chocolate colour. Light browns, running from coffee colour to saffron yellow, were obtained from different kinds of bronze. Copper gave a deep ruddy tint, coban and other combinations of gold and silver a pale greenish yellow, gold a rich, full yellow, shibu-ichi a dull grey, while white was obtained by the use of silver or polished steel.

In South Kensington there is a vase, a very fine specimen of this work in colours. The vase itself, beautifully shaped, is of iron, a warm chocolate brown. On this is inlaid a graceful design of birds and flowers, gleaming and sparkling in gold and silver, copper colour, green, blue, and violet.

In sword mountings this style of decoration was extensively used, and effects of great richness and beauty were obtained.

The tsuba, or sword guard, is a flat plate of metal, usually circular or slightly elliptical in form; but other styles, such as diamonds, squares, octagons, and irregular shapes decided by the exigencies of the design, are not uncommon. In size they vary from three to four inches in diameter, according to the size of the sword, and weigh from two to three ounces. The tsuba usually contains three openings--the central one wedge-shaped, through which the tang of the blade passes, and two other smaller openings, one on each side, to allow for the passage of the kozuka and kogai to their sheaths in the sides of the scabbard.

The earliest guards were made entirely of iron, and in many later tsuba this still forms the basis. But bronze in its various forms was also much used as a ground for ornamentation; and an alloy, sentoku, containing copper, zinc, tin, and lead, and of a soft yellow tint like brass, was another favourite material. In the latest periods other substances, such as bone, ivory, tortoiseshell, wood, leather, and papier-maché, the last three being coated with lacquer, were sometimes used.

One of the earliest methods of ornamenting the iron tsuba was what is known as kebori, or hair-line chasing. This was not executed with a graving tool but with a small chisel held in the left hand, and driven towards the worker with blows from a light hammer. This style of ornament reached its height during the sixteenth century, and may be seen in great perfection in the work of Goto Yujo.

A development of this style was the hira-zogan. In this lines were first engraved to a uniform depth and then undercut. Soft gold or silver wire was then hammered in, the wedge-shaped opening retaining it firmly without the use of any solder. Kebori-zogan was a combination of the two styles.

[Illustration: A GROUP OF TSUBAS (_From the Collection of Mr M. Tomkinson_)]

The kata-kiri-bori style depended for its effect not on the inlay of different metals but on designs in relief or intaglio. Often the design was defined by piercing, and the detail brought out by chasing and modelling in relief. In most cases the work was entirely that of the chisel and the hammer, untouched by any subsequent grinding or polishing.

In the kata-kiri-bori-zogan style--figured, sculptured, and encrusted work--we find the latest and most elaborate productions of the more modern schools, enamels being also used to add richness to the effect.

The iron, which forms the most usual material, is of exceedingly fine quality and of unusual softness. In many cases it was left rough from the hammer and punch, the marks, seemingly so careless, forming essential parts of the decoration. Etching with acids was sometimes adopted to bring out into greater prominence the twists and foldings of the wrought iron. In some cases, also, a surface grained like wood was obtained by welding together many strips of iron of different qualities and then treating with acid, which, of course, affected more strongly the softer layers.

It is doubtful when the tsuba first began to be an object of art, no specimens of an earlier date than the fourteenth century existing even in representations. Most of the tsubas on the older swords are much more modern than the blades to which they are attached. In the olden times, when the Samurai fell into evil days, he sometimes stripped off and sold the rich embellishments of his sword, retaining only the trusty blade.

Kaneiye, who worked about the end of the fourteenth century, is regarded as the first maker of tsubas artistically ornamented.

In the fifteenth century were produced many iron tsubas decorated with saw-cut silhouettes of birds, leaves, or animals, and with hammer or punch marks. Those last were probably the work of armourers, as in the case of Nobuiye of the Miochin family, whose iron tsubas were greatly valued. Some of these are of openwork, some with heads or masks in relief, others with punch marks. Another of the most famous workers in iron is Umetada, who lived about the middle of the seventeenth century.

Another of the fathers of the art was Goto Yujo, the founder of the Goto school, who lived between 1434 and 1512, and often worked from the designs of the painter Kano Motonobu. By this school, it is said, was introduced the peculiar ground of raised dots known as manako, or fish roe ground, and also the free use of gold, the excess of which marred so much their later work.

To the sixteenth century belong most of the beautiful specimens of saw-cut work in iron, chrysanthemums, kiri, and other crests being the favourite motives, though a number of conventional floral designs showing a strong Portuguese influence are also found.

In the early part of the seventeenth century the use of enamel in the ornament of the tsuba was introduced by Hirata Donin, and continued to be characteristic of the work of the Hirata family till the present century.

The time which produced much of the finest work of all is known as the Joken-in period, 1681-1708--the rule of the Shogun Tokugawa Tsuneyoshi--perhaps the most famous artist being Somin, who worked largely from the designs of the Kano painter Hanabusa Itcho. About this time the wonderful palette of colours in metal came into full use, and the range of subjects became more and more varied. As in the case of netsuké, so in tsuba one may read the whole history, legends, and mythology of Japan.

But the art had now passed its zenith, and a gradual degeneration set in, the work produced in later years being rich and ornate, but lacking the distinction of the earlier schools.

A few words must be said of the kozuka, the handle of the small knife, called the ko-katana, which is sheathed in the scabbard of the wakizashi, or short sword. The kozuka contains much beautiful ornamentation, and from its more sheltered position this is often of greater delicacy than that applied to the tsuba. The manner in which the problem of filling the long, narrow field is solved is a perpetual source of charm to the student of design.

The fuchi, or ferule, at the lower end of the handle of the sword, and the kashira, its lozenge-shaped cap, are also finely ornamented, the two combined usually forming one design.

South Kensington Museum has a varied collection of sword furniture, including many fine specimens, but, unfortunately, probably from lack of space, the objects are arranged in tall cases placed so closely face to face as to render the study of their contents almost impossible without the help of a candle.

CHAPTER VI

KERAMICS

Though the golden period of Japanese Keramic art was attained during the Tokugawa dynasty, 1603-1868, yet its origin is lost in the mists of antiquity. An interesting passage in an old Japanese chronicle shows that in the times of the Emperor Suwinin, about the beginning of the Christian era, the craft of the potter was the recognised industry of certain tribes. After giving an account of the death and burial of the Mikado's brother the record proceeds:

"On this they assembled those who had been in his immediate service, and buried them all upright round his sepulchre alive. For many days they died not, but day and night wept and cried. At last they died and rotted. Dogs and crows assembled and ate them. The Mikado, hearing the sound of their weeping and crying, felt saddened and pained in his heart. He commanded all his high officers saying: 'It is a very painful matter to force those whom we have loved during life to follow us in death, and though it is an ancient custom why follow it if it be bad? From now and henceforth plan so as to stop causing men to follow the dead.' On the death of the Empress, some time afterwards, the Emperor called his advisers together, and asked them: 'What shall be done in the case of the present burying?' Thereupon Nomi-no-Sukune advanced, and said: 'It is not good to bury living men standing at the sepulchre of a prince, and this cannot be handed down to posterity. I pray leave now to propose a convenient plan, and to lay this before the sovereign.' And he sent messengers to summon up a hundred of the clay-workers' tribe of the country of Idzumo, and he himself directed the men of the clay-workers' tribe in taking clay and forming shapes of men, horses, and various things, and presented them to the Mikado, saying: 'From now and henceforth let it be the law for posterity to exchange things of clay for living

men, and set them up in sepulchres.'"

The result of Mr W. Gowland's excavations of the dolmens, or burial mounds, which date from about 200 B.C. to 600 A.D., has been the discovery of a great deal of the ancient pottery--coarse ware unglazed and unpainted, and decorated only with simple patterns of lines incised in the clay while soft. The shapes, however, are often graceful and pleasing. In the dolmens were also found the rude terra-cotta figures of men above referred to.

For many centuries the art of the potter remained in very much the same primitive condition. A coarse ware sufficed for the domestic utensils of the common people, and lacquered vessels supplied the wants of the more luxurious. There is, indeed, mention of Korean potters having been brought over to Japan after the Empress Jingo's victorious campaign, and it is said that the art of glazing was practised at Hizen in the eighth century.

Little real advance, however, was made till the thirteenth century, when Kato Shirazayemon, better known as Toshiro, a native of Seto in Owari, and the father of Japanese pottery, appears. Dissatisfied with the results of the native kilns he visited China in 1223 to study the methods practised there, and after six years' absence returned to Seto. His pottery is a brown stoneware of firm and dense texture, and is covered with a glaze of a deep rich brown, sometimes mottled, altogether a great advance on the previous product of the country. The vessels made by him, mostly cha-ire, or tea-jars, used in the tea ceremony, are now valued at fabulous prices by the Japanese dilettante.

A certain authority states that Japanese history has been denominated by three factors: the sword, the tea-cup, and the paper house. The effects of the first and the last have been already indicated, and a few words here as to the second may not be out of place.

Legend ascribes a supernatural origin to the tea-plant. The Buddhist saint Daruma, he who sat wrapt in meditation for eight long years so that he quite lost the use of his lower limbs, once at his devotions was overpowered by sleep. On awakening, filled with shame at his frailty, he took a pair of scissors, and, snipping off the offending eyelids, cast them indignantly from him. They took root where they fell, and from them sprang a plant whose leaves had the magic quality of driving away sleep from weary eyes. In the temples it was much valued by the holy men, and a certain degree of ceremony or ritual attended its use.

It was in the time of Yoshimasa, in the fifteenth century, that the cha-no-yu, or tea ceremony, began to assume public importance. In his peaceful retirement, surrounded by artists and philosophers, it was practised by the ex-Shogun. The priest Shuko drew up a code of its rules, characterised by a severe and dignified simplicity. The room used was small, and plain to bareness, the utensils were unornamented, but, though to the ordinary eye crude and rough, were much prized by the connoisseur. Indeed, Yoshimasa often rewarded important services not by a grant of land but by the gift of a valued tea-jar.

A hundred years later Hideyoshi revived the ceremony, and its rules were revised by the famous philosopher Rikiu, the greatest of all the Cha-jin, or tea professors. Rikiu considered that the essentials of the tea ceremony were: "Purity, peacefulness, reverence, and abstraction." "It was important for the guest to come with clean hands, but much more so with a clean heart." Social rank was ignored: those present took rank according to their standing and reputation as Cha-jin. The most perfect courtesy and politeness governed all the proceedings. Frivolous or worldly talk was forbidden, and the conversation chiefly turned on the merit of the kakemono adorning the room, the flower decoration hanging before it, and the implements used in the ceremony.

A special ware was used for the tea bowls termed Raku ware. It is said first to have been made by a Kioto potter Ameya from a design by Rikiu, and so delighted Hideyoshi that he presented the maker with a gold seal, with the characters "Raku" (enjoyment) inscribed upon it, with permission to use it as a stamp. The ware is soft and porous, and covered with a thick, soft glaze. Not turned on the wheel but shaped by hand, it is rough and uneven in shape, and usually bears no ornamentation. Coarse and unsightly and rough as it may appear to the uninitiated, to the eye of the connoisseur it possesses many beauties; its irregular shape is comfortable to the hand, its soft glaze pleasant to the lips, and is said even to impart a flavour to the tea.

As the relaxation of the most cultured of the land, the tea ceremony had effects of far-reaching importance. As a corrective to the military spirit its glorification of the gentler virtues was invaluable, and to it in no small degree it is said the Japanese owe their character as the most courteous nation in the world. In art, though most strongly felt in the field of Keramics, its influence extended widely, affecting to no small extent the various branches of the minor decorative arts, and dominating, almost in a sense creating, the arts of landscape gardening and flower arrangement.

With Hideyoshi's revival of the tea ceremony, and the importation of Korean potters, the real history of Japanese Keramic art begins. Kilns were founded in many different parts of the country, and as each produced its own distinctive ware the development of these local art industries can best be traced separately.

The province of Hizen, lying in the south of the island of Kiushu, and the nearest point of the Korean mainland being only some two hundred miles away, it is natural that here the borrowed industry should first take root.

The most ancient kiln was erected at Karatzu as early as the seventh century, and a hundred years later glazing was there used for the first time in Japan. So famous did the Karatzu ware become that Karatzu-mono, "things of Karatzu," became the current name for all sorts of pottery. The Old Karatzu ware, however, was coarse and rough in quality, though some of its rich brown glazes were not without beauty.

In the sixteenth century Gorodayu Shonzui visited China and learned the art of making porcelain, and on his return to Japan brought a quantity of the clay with him. On the supply being exhausted, however, the manufacture stopped.

After Hideyoshi's invasion of Korea, towards the end of the century, many captives were brought back, including a Korean potter, Risampei, who discovered on the hills of Hizen a clay suitable for the making of porcelain. Kilns were erected, and the new manufacture started in earnest.

When the Dutch traders dealt with the port of Nagasaki the chief article of their export was the porcelain ware of Arita--known as Imari ware, from which port it was shipped to Nagasaki.

It is this ware that was distributed through Europe and gave the first and totally erroneous idea of the Keramic art of Japan. For the "Old Japan" ware, as it is called, was deliberately manufactured to suit the vulgar taste of the barbarous foreigner, who demanded copious and crowded decoration. It is almost ludicrous to compare it with the ware manufactured at the same time for home use. The one, the work of the artist Kakiyemon, is decorated with dainty and graceful designs, which in their reticence and simplicity are the embodiment of good taste; the other is quite un-Japanese in style, the ornament crowded and overloaded with colour, and often a mere gaudy jumble. But the "Old Japan" ware formed the models for half the factories of Europe, and we only need to turn to the Old Crown Derby porcelain to find its atrocities repeated with ludicrous fidelity.

In 1660 Prince Nabeshima established a kiln at Okawachi. It was reserved for the finest porcelain only, which was made for his private use, the sale being prohibited. Beautiful ware with a fine blue under the glaze was the chief product, and at a later date fragile imitations of flowers were made, of wonderful delicacy.

[Illustration: A GROUP OF PORCELAIN (_British Museum_) 1. Large Plate, Kutani ware (purple, blue, and green, on yellow ground) 2. Plate, Imari ware (design by Kakiyemon, red, blue, green, and yellow, on white ground) 3. Plate, Nabeshima ware (blue, on white ground)]

Another famous factory of Hizen is that at Mikawachi, where the Hirado ware, perhaps the finest of all Japanese porcelains, was produced. The factory was founded towards the end of the sixteenth century, and its first manufacture was an earthenware covered with a blue-grey glaze. In 1712, however, the discovery of fine porcelain stone was made in the vicinity, and in 1751 Matsura, the feudal chief of Hirado, took the kiln under his patronage, and for the next hundred years the ware may be assigned the first place among Japanese porcelains; for not only is the ground a pure and clear white, but the paté, free from gritty particles, is of a fineness of texture which is not possessed by other similar wares. With rare exceptions blue is the only colour used in its decoration, not the deep Chinese blue nor yet the rather weak tint of Nabeshima, but a delicate shade between the two. The favourite decorative motive was a scene with pine-trees and children at play. In ware of the finest quality seven children were introduced, in the second quality five, and in the third three. Many charming pieces were also made in plain white ware with pierced patterns or designs in relief, and at a later date the factory became famous for a delicate blue-and-white eggshell porcelain. Since 1830, however, the wares of the factory have declined greatly in quality.

Until within the last forty years the Keramic arts of Japan were only known to Europe by their porcelain, and only crude and inferior specimens of that, but the pottery and faience which merited even more attention were utterly unheard of. Since then matters have changed very much, and the faience of Satsuma is now the most sought after of all Japanese wares. But though Old Satsuma ware has become almost a household word, and there are few collections but boast of a specimen or two, the bulk of these objects are more or less clever imitations of a later date, excellent often in themselves, but not the rare and wonderful old Satsuma with its soft, ivory tint and its almost imperceptibly crackled glaze.

The original kiln appears to have been founded by Prince Shimazu Yoshihiro, chief of Satsuma, on his return from the Korean expedition, from which he brought back seventeen skilled Korean potters. In 1598 a kiln was opened close to his castle at Chosa, in the neighbouring province of Hiuga, which manufactured chiefly objects for the tea ceremony not unlike those previously made at Seto; but the glazes were of many varieties and very beautiful, some of them being exceedingly rich and brilliant. Prince Yoshihiro took great interest in the manufactory, settling handsome annuities on the most skilful potters, and stamping the finest pieces of work with his own seal.

In the year 1618 Boku, one of the original seventeen Korean potters, discovered in Satsuma a fine white clay or sand and other materials suitable for the manufacture of a finer quality of faience, and the result was a great improvement in the ware.

In 1630 the kilns were removed to Nawashiro, and by 1675 the ware had reached a high degree of excellence. About this time Tangen, a pupil of the great Kano painter Tanyu, was employed to paint or furnish designs for the potters, and Satsuma Tangen now constitutes one of the greatest treasures of the Japanese connoisseur. The decoration of such pieces as remain is slight and sketchy, the designs usually landscape, bird, and floral subjects, and the colours few and simple, often a reddish brown only being used.

Towards the end of the eighteenth century two Satsuma potters, Hoko of the Tatsumonji factory and Chiubei of the Tadeno factory, were sent by Shimazu Tomonobu, the chief of the clan, to travel all over Japan, visiting the different factories and learning the processes used in each. They visited Hizen, Kioto, Bizen, Owari, and other places, and particularly seem to have profited by their insight into the methods used in the production of the enamelled faience of Awata, for after their return, in 1795, may be dated a large increase in the manufacture of enamelled Satsuma faience, Nishiki-de, and it is this faience that is so widely known and valued as Old Satsuma.

The characteristics of this beautiful ware may be briefly noted. The paté is close as pipeclay and almost as firm and hard as porcelain. The chalky, porous nature of the newer work at once proclaims its late date. The old glaze is soft, lustrous, and mellow, with an exceedingly fine crackle. The decoration is simple, chiefly diapers and floral subjects in comparatively few colours, and the pieces are invariably small--tripod incense burners of about seven inches high being, perhaps, the largest objects. The large examples profusely decorated with human figures, peacocks, and other designs, are all of later date belonging to the period of forgeries which set in with the great increase of European trade after 1868.

[Illustration: VASE IN FORM OF LOTUS, SATSUMA FAIENCE (18TH CENTURY) (_From the Collection of Mr M. Tomkinson_)]

Of imitations there are many varieties. But first it may be mentioned that, prior to 1868, undecorated white faience was largely made at Satsuma, which was afterwards decorated at Tokio, but the refiring necessary completely takes away, in most cases, the distinctive and beautiful qualities of the crackled glaze.

The rarity of Old Satsuma ware may be judged from the fact that the average number of genuine pieces offered for sale in Japan during the last fifteen years has probably not been more than ten, and not more than half of these have left the country.

Though the Satsuma faience has the distinction of being the most beautiful ware produced in Japan, it is in association with the Kioto factories that we find most of the great names of Japanese Keramics--Ninsei, Kenzan, and Hozen.

The wares of Kioto may be divided into three classes: first, the Old Raku ware used in the tea ceremony; second, the decorated faience of Awata and the neighbouring kilns; and third, the porcelain which was the product of the early part of the nineteenth century.

During the civil wars which preceded the Tokugawa period the city of Kioto, though the seat of the Imperial Court, dwindled rapidly in importance; even the Mikado and his Kugé, or Court nobles, lived in dire poverty. Its tide of prosperity did not turn until the seventeenth century, and it is with the advent of Nomura Seisuke (also called Seiyemon and Seibei) that the great period begins. His native place was Ninnaji, near Kioto, and, taking the first syllable of that name and adding to it the first syllable of his own, he adopted the name Ninsei, with which he stamped his work.

As already described, the porcelain makers at Hizen had learned the secret of vitrifiable enamels as early as 1620, but it was guarded by them most jealously. It is said, however, that between 1650 and 1655 Kurobei, a Kioto dealer in porcelain, obtained the precious secret from an Aritu potter, Aoyama Koemon. The miserable man was immediately put to death by his irate lord; but the secret was out, and passed from the dealer to Ninsei, to the great future benefit of Japan. He applied it to the decoration of faience

with the most excellent results, for his taste and skill as a decorative artist were unrivalled among his contemporaries, and to his influence may be traced many of the most charming developments of later years.

A man of birth, he was not actually a potter by profession, and had, therefore, no fixed workshop, working at the factories of Awata, Iwakura, and Mizoro. He seems to have made no secret of the processes he had mastered, but gladly imparted them to those with whom he came in contact, and to this fact is doubtless due the rapid rise in the quality and increase in the output of the Kioto ware.

A word as to the Kioto kilns, which were all within a radius of a few miles, may be here advisable. The best known were Awata, Iwakura, and Mizoro; the others were grouped together under the general term Kyomizu.

Ninsei's faience is almost worthy to compare with the best ware of Satsuma, but is marked by a slightly darker colour, and is a trifle fragile in appearance, lacking the firm solidity of the Satsuma ware. Its crackle is fine and beautifully regular, giving the appearance of a covering of fine netting. His glazes range from a metallic black to a pearl white, through which a pink flush seems to spread.

His designs for decoration are simple and chaste, and the clear, pale greens and blues and rich reds of his enamels are of exquisite quality.

After Ninsei's death the next great name at Awata is that of Ogata Shinsei, or Kenzan, a younger brother of the still more famous Ogata Korin, painter and lacquerer, perhaps the greatest decorative artist Japan has produced. Kenzan was also a decorator of great power and originality. In complete contrast to the delicate harmonies of Ninsei, his designs are rough and bold, but his colour is superb and his decorative sense unerring. His work was at first confined to the coarser wares of the cha-no-yu, and here the singular force of his decoration harmonises well with the rude shapes, rough earthenware, and rich glazes, so that the Kenzan Raku ware is indeed a thing of beauty. But in faience he had equally great success. Once seen, his style can be recognised anywhere; a rough sketch of a landscape, a branch in blossom, a flight of birds, or the conventional shape of a flower, dashed in with seeming carelessness, but each touch placed in exactly the right spot for decorative fitness. A very fine specimen of his work--a brown pot decorated with an extremely rich design of peacock's feathers, blue-green and purple--may be seen in the British Museum.

The third great name of the Kioto group is that of Nishimura Zengoro, by Keramists known as Hozen. Born towards the end of the eighteenth century, he was one of a long line of potters. In 1801-3 he studied at the Awata factory, and soon his celadon and blue-and-white porcelain became celebrated. His fame attracted the notice of the feudal chief of Kiushu, who, in 1827, invited him to his province, and built a kiln for him in his private park, at which he produced the well-known ware called, from its stamp, Kairaku-en ware. Zengoro had made a special study of glazes, and the great beauty of this ware is the rich harmony of purple, blue, and yellow glazes which he obtained.

His versatility is shown by another ware which has an equally high reputation--the "Eiraku," or Kinrande (scarlet and gold brocade style). This is a porcelain ware of great delicacy and beauty, and usually made only in small pieces. The ground is of a soft coral red, upon which is traced a wealth of decoration in gold, with here and there a mass of rich blue.

Of the many other well-known names remaining among the Kioto potters only passing mention can be made. In many families the same stamp was used by one generation after another, rendering it difficult to distinguish their individual work.

The Kinkozan, Hozan, Taizan, and Tanzan families carried the traditions of Ninsei in Awata faience right down to the present day; while in the beginning of the nineteenth century the Dohachi family and the Kyomizu potter Rokubei followed in their decoration the newer naturalistic school. Mention must also be made of Shuhei and Kantei, potters of the end of the eighteenth century, who are regarded as the most eminent masters of the little Japanese tea-pot, or kuisu, and also of their contemporary Mokubei, a potter of so great ability that it is a pity he confined himself almost entirely to imitations of Chinese and other wares.

The history of the founding of the Kaga factories, which turned out the Kutani ware, is interesting and curious. Maeda Toshiharu, feudal lord of Daishoji, having discovered a bed of fine porcelain stone near Kutani, established a kiln about 1650, under the charge of two well-known potters--Tamura Gonzaemon and Goto Saijiro; but the venture was not a success owing to the lack of knowledge of the workers. Not to be outdone, Saijiro went to Hizen to learn there the secrets of porcelain making. The only way in which he was able to do this was by becoming a permanent member of the community. The manner in which he accomplished this was peculiar. He took service in the house of a potter, married a woman of the district, and worked there for several years. When he had learned all there was to learn he calmly deserted wife and family, and fled home to Kaga, where he imparted the needed information. Shortly after this time, about 1664, the Kutani potters were turning out wares of great beauty and individuality.

[Illustration: A GROUP OF VARIOUS WARES (_British Museum_) 1. Tea-Jar, by Toshiro I. 2. Tea Bowl--Raku Ware. 3. Tea Bowl after Ninsei. 4. Tea Bowl--Omuru, Kioto. 5 and 6. Tea Bowls, by Kenzan. 7. Kairaku-en Ware. 8. Kioto Ware. 9. Soma Ware. 10. Yatsushiro Ware. 11. Bizen Ware. 12. Banko Ware.]

Of these there were several kinds--the first, Ao-Kutani, was so called from the deep green glaze (ao = green) which was largely used in its decoration; and other glazes--yellow, purple, and soft Prussian blue--made up a rich, low-toned harmony of great beauty. In the second class of ware the Arita style of decoration was followed, except that the Kutani potter used blue under the glaze very seldom, and only in subordinate positions. Their chief colours were red--a soft, dull, rich colour varying from Indian red to a russet brown--and yellow, purple, and blue, supplemented by silver and gold.

Their designs were largely made by Morikaga, a pupil of Tanyu-- landscapes, birds, and flowers being the chief subjects.

A third famous ware of Kutani, which may be termed the red Kutani as distinguished from the green, had a ground of rich red, with diapers or medallions decorated in yellow, green, purple, and red enamels. Another style had the ground entirely of red, to which designs were applied in silver and gold, light green, and sometimes yellow and purple enamels.

For some reason the activity of the Kutani factory only continued for about sixty years, and during the next hundred years there followed a period of inaction. In the middle of the nineteenth century the manufacture was revived, both the red and the green Old Kutani wares being imitated, but with doubtful success. The modern colours, especially in the case of the red, lack the softness of the old, and are, comparatively speaking, harsh and glaring.

In 1827, at Edamachi Kanazawa, a kiln was founded which produced a beautiful faience known as Ohi-yaki, which is characterised by enamelled decoration of great delicacy and refinement.

The foregoing are the most important of the old Keramic arts, for the most distinguished products of the pre-Meji days may be summed up as the porcelain of Hizen and Kutani and the faience of Satsuma and Kioto.

A number of wares of lesser importance remain, chief among these being the Owari wares.

It will be remembered that it was to Seto in Owari that Toshiro returned after his visit to China in the thirteenth century, and founded the industry which entitles him to the name of “The Father of Japanese Pottery.” But from that time till the beginning of the nineteenth century little change took place in the character of the Seto wares, which continued to be stoneware and earthenware vessels, and little else. About 1801, however, a Seto potter visited Hizen, and after studying in the factories there returned, and founded a porcelain manufactory in Seto. Soon they attained great proficiency in the production of a blue-and-white ware which rivalled the products of Hizen. Their large pieces were particularly fine examples of firing, the technical difficulties to be overcome being enormous. The quality, however, of this ware rapidly deteriorated after 1850.

At about the same time a soft-crackled faience was made at Nagoya by a potter called Toyosuke. It is a soft-crackled faience of the Raku type, covered on the inside with a greenish white glaze decorated with bold floral designs, and on the outside with a thin coat of lacquer.

And now, for the remaining smaller branches of the industry a passing mention must suffice.

In the province of Bizen was manufactured a curious hard stoneware of a bluish grey colour, which chiefly took the form of vigorously modelled figures of gods, men, animals, and birds. Indeed, in the Bizen stoneware you find repeated in another form, but with the same vigour and originality, the achievements of the netsuké carver and the tsuba worker--Hotei, the pot-bellied god of contentment, being a favourite subject for treatment.

At Ise a wealthy amateur named Gozayemon founded a kiln in 1736, executing a ware which was known as Ko Banko. In the beginning of the nineteenth century a potter, Mori Yusetsu, conceived the idea of imitating this old ware. The imitator, however, was a much better artist than his prototype, and soon the new Banko ware was both widely different from, and of a much finer quality than, the old. This ware was worked on a mould, which was placed inside the article, and the clay pressed in with the fingers, the mould being afterwards removed in sections. The decoration was vigorous and artistic, consisting often of dragons, storks, etc., in relief.

In Higo a very beautiful ware called Yatsushiro was made. It is a dense faience coated with a film of pale grey clay by immersion in slip; the design, usually a delicate diaper, is then engraved and the lines filled in with white clay--the whole being covered with a

finely-crackled glaze.

Mention must be made also of the beautiful eggshell ware of Mino--delicate little saké cups and other vessels encased in envelopes of bamboo basket-work; and also of the Fujina ware of Idzumo--a faience decorated with beautifully executed designs of insects.

At Nakamura, in Iwaki, a kiln was opened in 1650, and here the ware known as Soma ware was produced. It is said that the Kano painter Naonobu, drew as a crest for Soma Yoshitane the galloping horse which in varying forms is seen on almost every piece of this ware.

Other lesser kilns are too numerous to mention, and existed in almost every province.

The British Museum possesses a good and varied collection of Japanese Keramic ware, but, unfortunately, the lack of a catalogue and the absence of any systematic arrangement, or even of proper labelling, takes away much from its usefulness to the student.

CHAPTER VII

LACQUER

The most wonderful of all Japanese arts is their lacquer-work, and, perhaps, in this more completely than in any other medium does the peculiar genius of Japan find expression. For the combination of qualities required for the production of a piece of fine lacquer are such as could have been found in no other people. And it comes to us with a shock of surprise that this work, so free and spontaneous and yet so delicate, is wrought in, perhaps, the most difficult and intractable material ever used by man, and built up slowly and by infinitesimal stages, layer by layer, through weeks and months of labour.

Even were the same brilliant faculty of design the gift of the European, the amazing and unfaltering precision of hand, and the limitless patience and unceasing care required by the technical processes, place lacquer-work far beyond his scope. It is only the Eastern who can combine the imagination of the artist with the technical powers and steady perseverance of the ant or the bee. For, indeed, in examining one of these marvellous Japanese works, so full of exquisite detail, so perfect in every part, one is irresistibly reminded of the honeycombs which form the monument of the humble insect worker; but where the one is the repetition of a single design fixed unalterably the other is free and spontaneous, the product of an ever-varying fancy.

It is difficult to imagine anything more perfect than a piece of really fine lacquer--the smooth, translucent surface pleasant even to the sense of touch; the design simple and slight, and sensitively placed so as to cause the blank spaces to form essential parts of the composition; and the whole glowing with soft gold of varying tints, or, perhaps, relieved with a boldly inlaid piece of mother-of-pearl, flashing with its brilliant irridescent hues.

To one who has seen specimens of the finest work--the glorious lacquer of old Japan--the words of the French critic, M. Louis Gonse, exaggerated though they may seem to the uninitiated, appear no more than a mere statement of fact: “Japanese lacquered objects,” he says, “are the most perfect works that have ever issued from the hands of man.”

But specimens of really fine lacquer are rarely to be seen outside Japan, where they are treasured in the collections of the wealthy. The British Museum possesses hardly anything which is really fine, South Kensington only a few small pieces. The bulk of the fine lacquer in this country is divided between a few private collections, chief among which is that of Mr M. Tomkinson at Franche Hall, near Kidderminster--a marvellous collection, rich in examples of all periods, and containing many exquisite pieces of work.

Though tradition says that lacquer-work was known in Japan as early as 392 B.C. it is supposed that the art, like others, came originally from China. At first its uses were purely utilitarian. Drinking-vessels were coated with lacquer to render them water-tight, and as the surface was hard as glass, and withstood considerable heat, it was also used largely for cooking and other household utensils. Indeed, this explains the slow development of the potter’s art in Japan, for where we would use glass or earthenware the Japanese used lacquered vessels. The armour of an old Japan warrior was often leather coated with lacquer; the sword was in a lacquered scabbard. He ate off a lacquered tray, drank out of a lacquered cup, and rode in a lacquered carriage.

The lac is a natural product--the gum exuded by the urushi-tree (_rhus vernicifera_), a species of sumach. The finest lac of all was obtained from very old trees; but, as the tapping and drawing of the sap resulted in the death of the tree, the supply had to be continually renewed, and so in mediæval times landowners were compelled by law to plant annually a certain number of trees, and

the export of lac was strictly forbidden. Even the Dutch traders of Nagasaki were not allowed to include it in their shiploads of porcelain and other wares, with the exception of a few pieces of inferior quality, specially manufactured, like the Imari ware, for the European market. It is safe to say that until the Paris Exhibition of 1867 no really fine lacquer had ever been seen in Europe.

[Illustration: OUTSIDE OF LID OF SUZURI-BAKO OR WRITING-CASE _In Green, Gold, and Silver, on Black Ground. Koma, Early 18th Century_ (_From the Collection of Mr M. Tomkinson_)]

At what date lacquer began first to be ornamented is unknown. The earliest known examples are preserved in the Todaiji and Shosoin temples at Nara, and date from the sixth and eighth centuries, and by the tenth century some very fine work had been produced. It was not, however, until the seventeenth century, when the country, under the firm hand of the Tokugawa Shogun Iyeyasu, after centuries of turmoil and civil war, had settled down to a peaceful existence that the period of the great lacquer workers set in. For in lacquer, as in many of the minor arts, the Tokugawa period marked the highest point of excellence. In the households of the wealthy Daimios the artist was freed from the more sordid cares of life. He need take no thought for the morrow, what he should eat or what he should drink, but could give his whole life to his art. And it was by the quality of his work, and not by the quantity, that he was judged. He had no idea of increasing his output in order to double his returns, but would spend months of labour on an object no larger than a few inches square. The larger pieces of work, exquisitely wrought outside and inside, the more delicate work being reserved for the inside, as there less liable to damage, in many cases represent the work of years.

For the process is long and tedious, and bristling with technical difficulties. First the wooden foundation for the box or other object to be lacquered is made of specially selected wood, generally a hard wood called by the Japanese hi-no-ki, which is not liable to warp, and admits of a very fine finish. These wooden objects are examples of beautiful cabinet making, often little thicker than cardboard, but fitting with great exactness. This foundation is strengthened with a layer of thin hempen cloth, and after laying on one or two preliminary coatings of a sort of paste mixed with lacquer, and carefully grinding down on a whetstone to ensure a perfectly smooth and even surface, the object is ready for the lacquering proper.

With a flat, short-haired brush--the hair used being generally human hair--the coating of lacquer is laid on in a thin, even layer, and the object set aside to dry, the period required for this varying from twelve hours to several days. Lacquer has this peculiar quality, that it dries best in a damp atmosphere, the moisture in the air seeming to draw out that in the lacquer. The articles are, therefore, placed to dry in a damp cupboard. On removal from the cupboard the surface is then carefully smoothed and polished by rubbing with charcoal. Coating after coating is added in this way, the final polishings being made with a fine ash of calcined deer’s horn, applied with the fingers.

Such are the complicated processes in the production of a piece of plain, unornamented black lacquer--the number of separate operations being no fewer than thirty-three, each one requiring the greatest skill and care; while for the production of one of the more elaborately ornamented pieces the number may extend to sixty or more, for the methods of decoration are many and varied, several being frequently applied to the same piece of work.

First of all we have the varieties of carved lacquer. There was the old Kamakura lacquer, in which the wood was first carved, then covered with a foundation of black lacquer, to which a red surface was added. In tsuishu and tsuikoku, carved red and black lacquer respectively, the article was first thickly coated with lacquer and afterwards carved. The process is said to have been invented by a Kioto workman in the fifteenth century, and in the time of Iyeyasu an artist, Heijuro, so excelled in it that he took the name Tsuishu Heijuro.

Chinkinbori is a form of incised lacquer, generally on a black ground. The lines are engraved with a rat’s tooth, as being less easily blunted than a metal tool, and are usually filled in with gold. Ninomya Johei, a physician of Yedo in the eighteenth century, was especially famed for this work. Raden is a form of lacquer in which mother-of-pearl and other shells, either in irregular or shaped pieces, are largely used, the colour effects obtained being of great brilliancy. A form of raden called aogai, a mosaic of green or purple irridescent shell crushed small, is especially used for the decoration of sword scabbards.

Togidashi is a style in which no rigid outline is used, but the forms left soft and blurred, being brought out by a series of rubbings. The greatest masters of this class of work were Yamamoto Shunsho and Koma Kiuhaku.

A curious and interesting form is guri lacquer. Here many layers of different coloured lacquers are applied, and the surface is then carved with conventional designs, in deep V-shaped incisions, exposing the different layers of colour.

The most gorgeous of all, however, is gold lacquer, the generic term for which is makiye, but this includes many varieties. In the same piece the gold will vary from solid masses standing up in relief to a dim, impalpable dust blending imperceptibly into the rich black ground. When the decoration is smooth and level with the ground it is termed hiramakiye, when in relief takamakiye. Kirikane is an inlay of small squares, hirakane or hirame an inlay of small pieces made from filings of gold flattened on an anvil. In okibirame, another inlay, the pieces are not dusted on but inserted singly by hand.

Giobu is a variety in which gold leaf is laid down on an irregular ground. This is covered with a deep red lacquer coloured with “dragon’s blood.” After drying the surface is rubbed down flat, and the gold is visible below, taking different tints according to its varying depth from the surface.

Nashiji (pear ground), one of the most famous styles, is a rich ground of powdered gold with the quality and texture of the rind of a ripe pear, and is largely used in conjunction with other forms of decoration.

A silver ground is also often used with charming effect. In Mr Tomkinson’s collection two very fine pieces of silver lacquer by Goshin, a lacquerer of the eighteenth century, deserve special mention. The ground is of a dim, misty grey, and on this is depicted a landscape with fir-trees on black lacquer. The nearest trees stand out bold and clear, those farther off seem embedded in the mist.

Another style largely used for sword scabbards was samé-nuri, shark-skin lacquer. The skin of a species of ray was stretched over the surface, the rough nodules filed down partially, and the whole covered with black lacquer. On the lacquer being rubbed down smooth and polished the nodules show as white discs on a ground of black.

Such are a few of the leading styles of lacquer; but numberless variations exist, and one piece often includes work in several different styles.

As already pointed out, the use of lacquer was at first entirely utilitarian; its adaptation to the purposes of ornament belongs to a later date. Perhaps the first ornamental lacquer was that applied to sword scabbards, horse furniture, and other warlike trappings. With the growth of a more peaceful civilisation came its application to the arts of peace.

[Illustration: A GROUP OF INRO (_From the Collection of Mr M. Tomkinson_) 1. Cock and Flowers (in gold and shell on brown ground). Kajikawa, 18th century. 2. Flowers and Paper Packets for Perfumes (ivory and gold, on black ground). Kajikawa, 19th century. 3. Pier of Bridge (in gold and shell, on black ground). By Kwoyetsu (Korin’s master). 4. Well overshadowed by Tree (gold and shell on black ground). Kajikawa, 18th century.]

A very favourite object for the lacquerer is the inro or medicine-box--a little box made in three or four separate sections and hung from the girdle by a cord. On the small surface here available he lavished all the resources of his art, and in inro we find many of the finest specimens of lacquer-work. Indeed, few things are more beautiful than a fine inro, with its rich but exquisitely judged ornamentation, for the Japanese artist possesses in a marvellous degree the power of working on a small field without loss of power or dignity. Even a specimen in plain black lacquer, unornamented, is a thing of beauty, pleasing to touch and to handle, and so perfectly made that the divisions between the sections are often invisible until they are pulled apart. This perfection of fitting is one of the tests by which the work of the old masters can be distinguished from that of their modern imitators.

Of the larger pieces of work the chief is the suzuri-bako, or set of writing materials. Then we have the jisshu kobako, or implements of the perfume game, comprising a cabinet containing the koro or miniature brazier, the kobako or perfume-box, fuda-bako or counter-box, and several other articles; and the sagé-ju, or portable picnic case, containing boxes, trays for sweetmeats, saké bottle, and so on.

Japanese authorities divide the history of lacquer into four eras--that of Nara, prior to 784 A.D.; Heian, 784-1185; Nanbokucho and Ashikaga, 1397-1587; Toyotomi and Tokugawa, 1597-1867. Of the earlier lacquerers little is known. In the fifteenth century, during the reign of the Ashikaga Shoguns, fine work was produced by Igarashi, the first of a line of lacquerers of that name. Little progress was made, however, until the beginning of the seventeenth century, when, after years of strife, the turbulent Daimios were finally subdued by Iyeyasu, the first of the Tokugawa Shoguns, and the country entered on a period of peaceful development. Towards the end of the seventeenth century began to rise the first of the great lacquerers, whose works are still the envy and wonder of their successors.

As in other branches of art, the traditions of this craft were handed down from father to son, and certain families became famed for lacquer. Two stand out especially as masters in the art--the Koma and the Kajikawa families.

The Komas were Court lacquerers for more than two hundred years, the first of the family, Koma Kiui, who died in 1663, being lacquerer to the Shogun Iyemitsu, and the line lasted until the nineteenth century.

The rise of the Kajikawa family was somewhat later; the first, Kajikawa Kujiro, one of the most excellent artists in lacquer, and famous for his giobu nashiji, lived about the end of the eighteenth century. He also was followed by a line of famous artists.

Both the Koma and the Kajikawa families were especially famous as inro-makers, and in this branch of the art it is difficult to say which was the greater. The Koma were remarkable for their coloured decorations, in which the design looked at by oblique light appears to be of gold but by direct light shows in brilliant colour.

One of the earliest lacquerers of whom there is any record is Honami Koyetsu, 1590-1637. Korin is said to have founded his style on that of Koyetsu, whose work certainly resembles to some extent that of the later and more famous artist. In Mr Tomkinson's collection are two inros by Koyetsu and Korin respectively, each decorated with the same design--the pier of a bridge in mother-of-pearl and gold--and treated in an almost identical manner.

The greatest of all names in lacquer is that of Ogata Korin, born 1660, died 1716. As a painter he is entitled to a place among the highest, but as a lacquerer he stands alone. His absolute originality and boldness of conception, his masterly instinct in design, and his splendid draughtsmanship are seen equally in his lacquer as in his paintings, but it is in his lacquer only that his unrivalled decorative powers find their fullest scope.

If the Japanese decorative artist has a fault it is that he is too pictorial in his methods, that he is almost invariably endeavouring to tell a story. But Korin does not lacquer like a painter, he paints like a lacquerer. He is first of all boldly and frankly decorative--the literary appeal is secondary. And though to one not thoroughly in sympathy with the artist there is much in his work that appears obscure or unintelligible, to the eye of the enthusiast these "obscurities" are splendid and triumphant pieces of decoration. Mere prettiness appealed little to Korin, but his work has on this account the greater dignity. Even when at first sight it startles and almost repels it soon grows on one; the longer one looks the stronger is its fascination.

[Illustration: A GROUP OF INRO BY KORIN (_From the Collection of Mr M. Tomkinson_) 1. Deer (in lead on gold ground) 2. Biwa in the Waves (gold and shell on black ground) 3. Fukurokujiu (lead and shell on gold ground) 4. Storks and bamboo (in pearl and lead on gold ground)]

The breadth of his treatment is the amazing thing about Korin's work, large masses of mother-of-pearl, the body of a bird, for instance, being laid in boldly in one piece, as in the inro with cranes here reproduced. Metals also, such as lead and pewter, were used just as daringly. But in the refinements of his art Korin was equally great. His gold mat grounds were especially famous, and were imitated by many of his successors. They are characterised by a steady, rich, full tint with a glow in it, and vary from a silvery to a deep copper hue, and in texture from an impalpable dust to an inlay of square dice. Then from the solid mat the gold will thin out into the lacquer till lost in its depths. His bolder work earned the same sincere flattery of imitation, but the imitator can easily be detected. Mr Tomkinson's collection is especially rich in fine specimens of Korin's work, and through his courtesy I reproduce one or two characteristic examples.

Ritsuo, a pupil and contemporary of Korin, was born in 1663. Like his master, he was celebrated in many branches of art; not only a lacquerer, he was a skilful metal worker, a carver, a potter, and a painter. In his more richly decorated lacquer, that known as hiaku-ho-kan (a hundred precious things inlaid), he often introduced pieces of his own pottery. His work is very distinctive, bold, and strong, with firm modelling and rich, full colouring. In his suzuri-bako he appears to special advantage; the outside of the box rough and bold, the inside enriched with work full of delicacy and refinement. One fine example in Mr Tomkinson's collection has the outside in rough wood, the grain being made more prominent by the soft parts having been eaten out with acid. In the centre the wood is cut away, and a figure of Daruma, in pottery, is inlaid. The inside of the lid is a complete contrast to the rudeness of the exterior, and is wrought with the utmost delicacy and beauty of finish.

Ritsuo's pupil Hanzan also did very fine work in a similar manner. South Kensington Museum possesses a very beautiful little inro from his hand, inlaid with fish in rose-tinted mother-of-pearl.

Of modern masters the most famous is Zeshin, born in 1807, died in 1891, and both as a lacquerer and painter he was worthy to rank with his great predecessors. Zeshin is almost the only one of the moderns whose work could at all compare with that of the old masters, but he lived and died in poverty and obscurity.

Modern industrial conditions hardly admit of the same patient workmanship--months, and perhaps years, being expended on one article. Speedier results are required, and this causes the use of inferior but quicker drying lac, which has neither the beauty nor the durability of the finer quality. A proof of this was given after the Vienna Exhibition of 1872. The vessel which was taking back a number of pieces of lacquer, old and new, was wrecked off the coast of Japan. Eighteen months after the pieces were recovered, the new utterly ruined, but the old work entirely unharmed, bright and untarnished, as if fresh from the maker's hands.

CHAPTER VIII

LANDSCAPE GARDENING AND THE ARRANGEMENT OF FLOWERS

No review of Japanese art, however superficial, can pass over without mention one of the most interesting of all its phases--the application of its conventions to the living and plastic forms of nature in the sister arts of landscape gardening and the arrangement of flowers. And here, as in other departments, the Japanese artist does not seek dully and slavishly to copy nature, but by a frank and dexterous use of these conventions he endeavours to suggest its spirit. By this departure from mere literal truth he attains a wider fidelity to nature. In the limited space at his disposal he knows that he cannot transplant a piece of natural scenery--he must work to scale--but his miniature rocks, trees, hills, and streams are so exquisitely proportioned as to express within the area of a few yards the breadth and expanse of nature.

So, too, in flower arrangement, the master secures the appearance of naturalness by the most careful and daring manipulation. Twigs and stems are twisted and broken, leaves and petals even shaped and cut, to produce the effect apparently so spontaneous, so free from artificiality.

And the reason is obvious. The defect or incongruity that would pass unnoticed amid the wealth and profusion of the living plant, balanced with superb ease by countless other points of interest so that the eye could not dwell on the deformity, when transferred to the narrower field of the flower vase, stands out with awful distinctness, and assumes an importance which formerly it did not possess. The artist dare not take the liberties which Nature allows herself. Her keyboard is limitless, but his harmonies must be built up of a few carefully selected chords.

The rise of both arts dates from that wonderful period of awakening--the coming of the Buddhist priests in the sixth century. The first gardens were those of the old Buddhist temples; the first flower arrangements were placed as offerings before their shrines.

Among the earliest examples of landscape gardening were the temple groves of Biodo-In at Uji, and Todaiji and Kofukuji at Nara, and this old style of temple garden, simple and severe, was called Shinden-Shiki, but little is known regarding the details of its arrangement.

With the Kamakura period, from the twelfth to the fourteenth centuries, we come to more familiar ground. Then the landscapes took a freer form--hills and valleys, lakes, streams, and waterfalls being represented. A curious form was the Kare-sansui, or dried-up water scenery, where the bed of a stream or the hollow of a lake was shown dry, as if in time of drought, and this style was usually combined with a bare mountain or moorland scene.

But a great impetus was given to the art when, in the fifteenth century, Yoshimasa, retiring from active life, and surrounded by a group of artists and sages, revived the ancient tea ceremony, and made it the nucleus of so many forms of art. The wide-reaching effects of this quaint ceremonial on art generally have already been indicated in a previous chapter. A special form of garden was devoted to its use; while also the art of flower arrangement flourished for long merely as an adjunct of the cha-no-yu.

In the first group of Cha-jin, or tea professors, were Shuko (the teacher of Yoshimasa), Showo, and the famous artists No-ami and Oguri Sotan; while a little later we have the names of Gei-ami, So-ami, and later still Senno Rikiu and Enshiu. So-ami was one of the greatest masters of landscape gardening, and in his quiet and dignified compositions one sees the hand that produced the delicate landscape paintings of misty hill and lake. Examples of his gardens exist to this day, the best known being that of the Silver Pavilion at Ginkakuji, which was laid out about the year 1480.

A hundred years later Enshiu was the founder of a new school, which afterwards became very popular. One of his greatest works was a palace garden near Kioto, through which flowed the river Katsura, and so highly esteemed was this garden that for one hundred and fifty years after his death not a stone or shrub was altered.

During the luxurious Tokugawa period it became the custom for the wealthy Daimios to have their gardens laid out by well-known artists; and the art grew still more in importance, a modern style being introduced by Asagori Shimanosuke of Fushimi in the early part of the nineteenth century.

The training of the landscape gardener was long and arduous, for it was by no means the same thing to compose an actual landscape as to paint one. The novice was sent direct to nature to sketch and study natural forms, not, as in painting, from one point of view only, but so as to realise how a scene would appear from all sides.

In designing a garden the first step was a careful survey of the site; its drainage, levels, size, and shape had all to be taken into consideration. The aspect then was chosen, and this was generally south or south-east, so as to be sheltered from the cold west wind, though near Tokio a vista to the west was always left open commanding a view of Mount Fuji. Then the style of the garden had to be decided. Was it to be a hill garden or flat plain land? Was it to follow the “Rocky Ocean,” the “Wide River,” the “Mountain Torrent” or the “Lake Wave” style? The character of the surrounding country would largely determine the answer to this question, for a garden was designed to fill harmoniously its place in the natural scene. The artist also, while endeavouring to obtain a result that would look well from any point, had to bear in mind that the best view of all should be from the house itself.

A striking characteristic of Japanese gardens is that water, in the form of cascade, lake, or stream, is almost universally present, its cool and refreshing properties being considered well-nigh indispensable.

The main levels fixed, the hills and valleys modelled, the next important feature consisted of the rocks and stones which represent the crags and precipices of nature. Great care is taken in the selection of these, which are termed the bones of the garden. Certain stones, which are highly valued are often brought great distances, the larger ones sometimes carefully split to render carriage more easy, and pieced together again on their arrival. Fancy prices were paid for such stones; and, indeed, to such a height did this form of extravagance attain, that early in the nineteenth century an edict was issued limiting the price to a certain sum.

The size of the garden, which varied from about fifty square yards to a few acres, gave the scale of the stones, and these again in their turn fixed the size of the shrubs, the trees, the fences, and other furnishings of the garden. In a large garden there were no less than one hundred and thirty-eight of these stones, each with its special name and purpose assigned to it.

In the arrangement of the trees, shrubs, and flowers a regular or symmetrical arrangement was avoided, the growths and forms of nature were carefully followed, and the result made to appear as free and unstudied as possible. Contrasts of form and line, and of colour in the foliage, were sought after. No garden was deemed complete without maple-trees, so placed that the light of the setting sun would enhance the richness of its crimson leaves. Deciduous trees were not so largely used as evergreens on account of their bareness in winter; but exceptions were made in the case of the plum and the cherry, so highly prized for the beauty of their blossom.

Flowers were chiefly grouped round the house, and were sparingly distributed among the foliage; but here again we have exceptions in the case of the iris and the lotus, which were used in large masses with gorgeous effect.

Miniature pagodas appeared among the trees in the larger gardens, little bridges crossed the streams, and large stone lanterns cast a dim and mysterious light over the scene when darkness had fallen.

But now let us turn to the sister art. The love of flowers has long been a characteristic of the Japanese people. As long ago as the ninth century the Emperor Saga held garden parties during the flowering of the cherry blossom, at which the literati of the day composed verses in honour of the flowers; and now, after the lapse of ten centuries, the transient glory of the cherry blossom is still a national festival, observed alike by the rich and the poor.

Nowhere but in Japan has the flower motive been so extensively used in art or with such grace and charm. The Japanese flower paintings stand in a class by themselves, beside which all others seem clumsy and coarse, alike in conception and execution, but it is in the applied arts that their fancy is allowed to run riot. In lacquer floral designs are wrought wonderfully in gold or inlaid in mother-of-pearl; in metal they appear in chasing, embossing, inlaying, and many other forms; they form the chief decorations of pottery and porcelain; but it is perhaps in the textile fabrics of Japan, in the gorgeous silk brocades, that they are seen in their

greatest glory.

This being so, need we be surprised that in Japan the arranging of living flowers has for hundreds of years been recognised as a fine art, has had its schools, its laws, and its traditions, and has numbered among its exponents such great artists as So-ami, Oguri Sotan, and Korin? The flower artist, they say, “must be thoroughly imbued with a sympathetic feeling for the character, habits, virtues, and weaknesses of the members of the floral kingdom from which he seeks his material, till he possesses the same love and tenderness for their qualities as for those of human beings.”

And so to the arrangement of flowers the Japanese bring an enthusiasm, a delicacy, and a refinement of dainty pedantry that, even in its most stilted and artificial forms, is full of charm, for the spirit underlying the formality and giving life to the most mannered productions is this genuine and reverential love for the beauties of nature. It is related of Rikiu, the famous flower artist and philosopher, that he once observed a fence covered with a beautiful growth of convolvulus. After standing for a while rapt in admiration he plucked one flower and one leaf, which he carefully arranged in a vase. “Why so humble,” asked his friends and pupils, “when the whole plant is there at your disposal?” “Nay,” answered the master; “it is impossible to rival nature in magic of design, and so any artificial arrangement should be marked by modesty and simplicity. But even one leaf and one flower are sufficient to call for admiration.”

The Japanese art of the arrangement of flowers deals not only with blooms but also with many non-flowering plants characterised by a graceful habit of growth. The effects aimed at are pre-eminently those of line and balance, colour being more or less subordinated to these qualities.

The earliest flower studies, placed as offerings before the shrines in the temples, followed a style of erect composition known as the Rikkwa school, and with their vertical central mass and supporting side groups approached more nearly to symmetry than is usual in Japanese art.

In the later styles symmetry was carefully avoided, and, perhaps, to no department of art does the style of asymmetrical yet balanced composition seem more suited than to those delightful arrangements of freely growing natural forms.

The most popular school is that of Enshiu, which groups the essentials under three heads. First, the quality of giving feeling and expression to compositions, for the Japanese artist is no mere copyist of nature; each group must mean something, must convey some idea. Second, truth to nature in the sense of presenting correctly the style of growth of the plants used; and third, truth to nature in the strict observance of the laws of season and locality.

The different parts of the composition have each a special name, as also have many of the faults into which the novice is liable to fall.

[Illustration: A FLOWER COMPOSITION]

Nagashi, the arrangement of long, streaming sprays on each side of a group, is, as approaching the symmetrical, especially to be avoided. “Window-making,” the crossing of stalks in such a manner as to give the appearance of loopholes, and “lattice-making,” where the crossing suggests lattice-work, are both grave faults, as is also any suspicion of parallelism in the main lines.

It is not sufficient either that the finished study should look well from the front. It must bear the test of examination from all points of view.

There are also distinct rules regarding the vessels employed to hold the compositions. Sometimes beautifully wrought bowls of bronze are used, sometimes vessels of wood or porcelain, sometimes a simple wicker basket.

The shallow bronze bowl is the most usual, as in it little vices of wood may be conveniently fixed across to hold together the stems, and metal crabs, dragons, tortoises, and frogs are often used to hold the cuttings in position, and at the same time form part of the design. Sometimes the vessel is made in the shape of a boat, a style said to be first inaugurated by So-ami, and since forming a class of composition by itself.

A favourite combination is a rough wooden tub used for horses to drink from and a bronze horse’s bit. Its use dates back to a time when a famous general of old, during one of the duller intervals of a campaign, employed his leisure in composing a flower study, using as vessel and vice the only articles at his disposal.

Holders of bamboo are used in various forms, as many as forty-two different methods of cutting and notching the hollow stem being recognised. Some of the names of these are delightfully expressive--such as “lion’s mouth,” “singing mouth,” “flute,” “stork’s neck,” “conch shell,” and, most imposing of all, “cascade-climbing-dragon’s form.”

The plants themselves are grouped in many grades. Seven--the chrysanthemum, the narcissus, the maple, the wisteria, and the evergreen rhodea--are of princely rank, and form a veritable aristocracy of flowers. The iris, also, is of equal rank with the foregoing, but, owing to its purple colour, must never be used at a wedding.

Then, again, within the same species, the flowers take rank according to their colour, in most cases the white bloom ranking highest. Among chrysanthemums, however, the yellow takes precedence, with the peach and cherry pale pink, and with the camellia and peony red.

Certain plants, also, must never be used, and this “Index Expurgatorius” includes all strong-smelling or poisonous plants, and a long list comprising the aster, the poppy, the orchid, the rhododendron, and many others.

Male and female attributes are also applied to plants in many ways. The front of leaves is male, the back female; red, purple, pink, or variegated flowers are male; blue, yellow, and white female. So that a flower composition in Japan, apart from its intrinsic beauty, bears a wealth of symbolic meaning.

In all important rooms there is an ornamental alcove or recess, called the toko-no-ma, with raised floor polished and lacquered, and a handsome corner pillar of rare wood. On the back wall is hung the kakemono, or in some cases a pair, or set of three, and on the dais before it, or suspended from above, is placed the flower study. In this recess are displayed, one at a time, the choicest art treasures of the house, and in front of it is the place of the honoured guest.

There is an etiquette even in looking at flower studies, and in praising them only appropriate epithets should be used, always softly expressed. White flowers are “elegant,” blue “fine,” red “charming,” yellow “splendid,” and purple “modest.”

But the greatest compliment that can be paid to a guest on such an occasion is to ask him to make an extempore arrangement himself. And here the ceremonial is delightful in its graceful formality. The host brings a tray with vase, cut blooms and sprays, scissors, knife, and a little saw. If the vessel brought be a very valuable one the guest modestly protests that he can produce nothing worthy of so fine a setting, but, on being pressed by his host, should comply with his wishes. The host then removes the kakemono, for to allow it to remain would impose upon the artist the task of designing his group in harmony with it, and with the rest of the company withdraws to an adjoining room until, the work being completed, the guest summons them, having placed the scissors beside his composition as a silent request for the correction of its faults. When his host enters he apologises for the imperfections of his work, and begs that the whole may be removed. The host in his turn assures him that in beauty it is all that could be desired, and so the delicate interchange of compliments goes on.

Not the least attractive feature of this gentle art is the evanescent nature of its charms. The painter, the sculptor, the artist in lacquer or in metal, works for posterity: hundreds of years hence his fame may be greater far than it is to-day. But the artist in flowers can hope for no such permanence in his work, its creations are verily but “the lilies of a day,” his modest task but to give sweetness and beauty to the passing hour.

TRANSCRIBERS' NOTES

Missing or incorrect punctuation, as well as obvious spelling errors (e.g., 'stonger' → 'stronger'), have been silently corrected.

The original spellings of Japanese names (people, places, and things) have been retained and have not been updated to reflect modern orthography.

In this text version, "_" was used to indicate words which were in _italics_ in the original text and all small caps have been replaced with capital letters.

THE

WATCHMAKERS’ HAND BOOK

INTENDED AS A WORKSHOP COMPANION FOR THOSE ENGAGED

IN WATCHMAKING AND ALLIED MECHANICAL ARTS

BY CLAUDIUS SAUNIER

ILLUSTRATED AMERICAN EDITION

REVISED AND ENLARGED BY HENRY G. ABBOTT WITH SPECIAL REFERENCE TO THE WANTS OF AMERICAN WORKMEN

CHICAGO: GEO. K. HAZLITT & CO., PUBLISHERS. 1894.

COPYRIGHTED 1892, BY GEO. K. HAZLITT & CO.

PREFACE.

M. Saunier's writings occupy an unique position in Europe, as works of reference for all who are engaged in watchmaking, and it may not be out of place to observe that the American edition of his treatise promises to take a similar place among English-speaking communities.

A glance at the index will show that the information given is essentially practical in its character, and such as will be of use to the watchmaker in his daily work. The volume is thus in no sense an abridgment of the original edition, but on the contrary, it contains much more matter than the original work.

In recent years the work of the ordinary watch repairer has undergone considerable change. The apprenticeship he serves, if indeed it can be called a real apprenticeship, is shorter than formerly. The immense number of badly constructed watches that he is called upon to put in going order for a trifling remuneration, compels him to replace the older methods of procedure by others, whenever by so doing time can be saved. From this point of view, then, the value of the present Hand Book can hardly be over-estimated, since it contains, in a readily accessible form, many details as to the working of metals, and descriptions of various practical operations, new and improved forms of tools, etc.

But the volume will be found of daily use to a wider circle of workers than those above referred to. We believe that there is hardly a branch of the watchmaking trade which may not benefit by the numerous practical details that are given; indeed, although the work is specially designed for the use of watchmakers, a great portion of it will be seen to be no less applicable to other mechanical arts.

M. Saunier's original works, the _Guide-Manuel de l'Horloger_, and _Recueil des Procedes Pratiques_, which appeared as separate volumes, have been incorporated in this American edition, a large amount of additional information being at the same time added. As the second contained many details that more properly belonged to the first, and _vice versa_, it has been thought desirable to remodel the whole, and, as will be seen from an examination, the six parts that constitute the work are distinct in their character.

With a view to further facilitate the use of this Hand Book as a work of daily reference, an unusually full index has been added, which the reader is recommended in all cases to consult, and no effort has been spared to make the cross references in the body of the work as complete as possible.

It seems desirable here to give some explanation in regard to several of the practical methods described. Every watchmaker will at once recognize that recipes are included which are of the nature of makeshifts, and that it would in many cases be better to replace a piece by a new one rather than to repair it in the manner indicated. But, on the other hand, it has been felt that the work will often be appealed to by those who, from various circumstances, may be prevented from making or procuring a new part that will suit the watch under repair, while those who are not so situated will have no difficulty in deciding for themselves as to which method to adopt.

The original work of M. Saunier, and the English edition, both had the illustrations in the back of the work, which necessitated considerable inconvenience when consulting them. In this edition we have ventured to insert the illustrations in the text that describes them. The antiquated tools, like the bow, bow-lathe, the turns and mandril, have been omitted, and the modern foot-wheel, lathe and accessories substituted.

HENRY G. ABBOTT

ARITHMETIC, GEOMETRY, DRAWING, ETC.

ARITHMETIC.

=1.= We often hear the theory advanced that in this country, at the present day, it is not necessary to have a knowledge of arithmetic, geometry, drawing, etc., because our interchangeable system of manufacturing watches, makes all knowledge in these lines superfluous, and that without any knowledge of arithmetic or geometry a man may become a thorough master of watchmaking. This is a mistake that too many of our young men make. The fact that the leading watch factories of the United States have adopted the interchangeable system, of course lessens the number of parts which the repairer will have to make and fit, but it by no means alters the situation as regards the repairing of foreign-made watches, nor even the changing of American watches from key to stem-winders. Without a thorough knowledge of arithmetic and, at least, an insight into the principles of geometry, no young man can hope to become a first-class watchmaker in the true sense of the word. Without these accomplishments he will be deprived of the pleasure of reading understandingly the best literature of the day, the works of those who are best fitted to impart knowledge to the members of the trade.

With a knowledge of geometry he will be able to comprehend the works of the best authors, to ascertain the dimensions of solid bodies, and be in a position to apply the rules that form the basis of linear drawing. Every watchmaker, worthy of the name, should be able to make and understand the drawing of any machine, or of any horological instrument. Many inventors, and even ordinary workmen, would avoid a large amount of hard work, often useless, and occupying much time, if, instead of at once putting an idea into practice with brass and steel, they were able as a preliminary, to make for themselves a correct design drawn to scale.

=2.= It is taken for granted that the reader is familiar with the rules of arithmetic at least, and we will touch upon some points in algebra and geometry that it will be well to mention. Should the reader have no knowledge of arithmetic, algebra and geometry, we would advise him to take up these studies during his leisure hours, using some of the standard text books for that purpose.[1] Besides possessing a knowledge of prime numbers, numbers which have no divisors but unity and themselves, the watchmaker should be able to determine the greatest common measure of several numbers, a rule which is of great importance in calculating a train of wheels that is complicated.

We shall confine our attention to the methods of extracting square roots and proportions, the rules for which may have been forgotten, owing to their being less frequently employed than the more common rules of arithmetic; they are of frequent use in horology.

SOME SIGNS EMPLOYED IN CALCULATIONS.

=3.= The sign of addition is an erect cross, +, called _plus_, and when placed between two quantities it indicates that the second is to be added to the first. Thus, 5 + 3 equals 8.

The sign of subtraction is a short horizontal line, -, called _minus_, and when placed between two quantities it indicates that the second is to be subtracted from the first. Thus, 8 - 3 equals 5.

The double sign, ±, is sometimes written before a quantity to indicate that in certain cases it is to be added and in others it is to be subtracted. Thus 5 ± 3 is read 5 _plus or minus_ 3.

The sign of multiplication, ×, when placed between two quantities indicates that the first is to be multiplied by the second. Thus, 3 × 5 equals 15.

The sign of division is a short horizontal line with a point above and one below, ÷, and when placed between two numbers or quantities it indicates that the first is to be divided by the second. Thus, 6 ÷ 2 equals 3.

The sign of equality is two short, horizontal, parallel lines, =, representing the words equal to. Thus, 6 ÷ 2 = 3.

Inequality is denoted by the angle >, the opening always being toward the larger number or quantity; thus, in 12 + 7 > 14, the sign >, indicates that the sum of 12 and 7 is greater than 14, and the whole expression is read, 12 plus 7 is greater than 14. The expression 9 < 4 + 7 is read, 9 is less than 4 plus 7.

A parenthesis, (), denotes that the several numbers or quantities included within it are to be considered together, and subjected to the same operation. Thus, (10 + 4) × 3 indicates that both 10 and 4, or their sum, are to be multiplied by 3.

A horizontal vinculum, ------, placed over the numbers or quantities, is frequently used instead of the parenthesis. Thus, @2 + 4 + 6@ × 7 is equivalent to (2 + 4 + 6) × 7.

Division is more usually indicated by a line between the two figures, the dividend being written above and the divisor below the line. Thus, ¹■/■ indicates division, the same as 16 ÷ 8.

Algebra is that branch of mathematics in which the operations are indicated by signs or symbols, and the quantities are represented by letters.

The sign of ratio consists of two points like the colon, :, placed between the quantities compared. Thus, the ratio of _a_ to _b_ is written _a_ : _b_.

The sign of proportion consists of a combination of the signs of ratio. Thus,: :: :. The first two and last two dots are read _is to_, while the four in the middle are read _as_. Thus, if _a_, _b_, _c_, and _d_, are four quantities which are proportional to each other, we say _a_ is to _b_ as _c_ is to _d_, and this is expressed by writing them thus:

_a_ : _b_ :: _c_ : _d_.

POWERS AND ROOTS.

=4.= The power of a number is the product formed by successive multiplication of the same number by itself. Thus,

2 × 2 = 4, the second power or square of 2. 2 × 2 × 2 = 8, the third power or cube of 2. 2 × 2 × 2 × 2 = 16, the fourth power of 2, etc.

An exponent is a number written above a quantity, at the right-hand, to indicate how many times the quantity is to be taken as a factor, as 6^3 = 6 × 6 × 6.

The root of a quantity is a factor which, multiplied by itself a certain number of times, will produce the given quantity. Thus, in the above examples 2 is the square root of 4 and the cube root of 8.

The radical sign, √, indicates that the root of the quantity placed under it is to be taken, and the index of the root is expressed by a little figure placed outside of the bend. If a square root the index figure is usually omitted.

√4 = 2 or ²√4 = 2 and ³√8 = 2.

=5. Extracting the square root of whole numbers.= [2] I. Point the given number off into periods of two figures each, counting from the units place to the left. For example, we wish to find the square root of 399424, we point it off thus: 39,94,24.

II. Find the greatest perfect square in the left-hand period, and write its root for the first figure in the required root; subtract the square of this figure from the first period, and to the remainder bring down the next period for a dividend. Thus:

39,94,24(6 36 -- 394

III. Double the root already found, and write the result on the left for a divisor; find how many times this divisor is contained in the dividend, exclusive of the right-hand figure, and place the result in the root and at the right of the divisor. Thus:

39,94,24(63 36 -- 123 394

IV. Multiply the divisor thus completed by the last figure of the root; subtract the product from the dividend, and to the remainder bring down the next period for a new dividend. Thus:

39,94,24(63 36 -- 123 394 369 --- 2524

V. Double the right-hand figure of the last complete divisor for a new divisor, and continue the operation as before. Thus:

39,94,24(632 36 -- 123 394 369 --- 1262 2524 2524

PROPORTION.

=6.= It is often convenient to express the relations of qualities in the form of a proportion and from the proportion derive an equation.

Ratio is the quotient of one number divided by another. Thus the ratio of 30 to 6 is ³■/■.

=7.= Proportion is the equality of ratios: Thus if ³■/■ = 5 and ■■/■ = 5 then we may state that ³■/■ = ■■/■ or the proportionality is usually expressed (=3=) thus:

30 : 6 :: 40 : 8

and this constitutes what is called a geometrical proportion, and 30 and 8 are called the extremes and 6 and 40 the means.

=8.= The product of the extremes is always equal to the product of the means. Thus: 30 × 8 = 6 × 40 = 240. Hence it follows that if we only know three terms we can always determine the fourth, or unknown term, which is usually represented by the letter _x_. Thus in the proportion

12 : 3 :: 16 : _x_

we find the product of the means, or 3 × 16 = 48; this product divided by 12, the known extreme, gives us the value of _x_, or the unknown extreme, as equalling 4.

=9.= If we know the two extremes and only one of the means the same rule is applied. Thus in the proportion

20 : 5 :: _x_ : 25,

we have: 20 × 25 = 500. ■■■/■ = 100, the value of _x_.

ELEMENTS OF PRACTICAL GEOMETRY.

=10.= The object of geometry is to measure the extent of bodies. A body has three dimensions, _length_, _breadth_ and _thickness_, and one of these latter is sometimes termed _weight_ or _depth_.

Either dimension taken by itself is measured by a straight line.

When the extent of a body is expressed by combining any two dimensions, it is termed _area_ or _surface_, and when three are employed we obtain the solid measure or _volume_.

Plane geometry only takes cognizance of figures situated in one plane or surface, and therefore only possessing two dimensions; _solid_ geometry, however, regards bodies as having all three dimensions.

Two lines are parallel when their distance apart is the same at all points. The same is also applicable to parallel planes.

Two lines or planes meeting each other will form an _angle_. The point at which they meet or intersect is termed the _apex_ or _summit_ of the angle.

A straight line is _perpendicular_ or _at right angles_ to another straight line, or to a plane, when all the angles which it makes with that line or plane are equal.

A _circumference_ of a circle is a curved line _l c d f_ (fig. 1,) such that all its points are equally distant from an internal point, _o_, termed the _center_. The _circle_ is the space enclosed by the circumference.

It will be noticed that in geometry these two words are distinguished, although they are frequently referred to as identical. Thus, the rim of a wheel or balance is generally termed a circle.

Two circles (_l c d f_ and _b r a_, fig. 1,) described from the same center are said to be _concentric_. When their centers do not coincide they are called _excentric_ with regard to one another.

Any portion of a circumference, such as _f n d_, is termed an _arc_ of the circumference, or, more commonly an _arc of a circle_.

A _chord_ is a straight line, _f d_, which unites the two extremities of an arc. When the chord passes through the center of a circle it is termed a _diameter_.

The _radius_ of a circle or circumference is a straight line drawn from the center to the circumference; and all the radii that can be thus drawn are equal. A diameter is, then, always double the radius, and, conversely, the radius, is always half the diameter.

A _tangent_ is a straight line that only touches a circumference at one point, as _g l_ (fig. 1); whereas a _secant_ cuts the circle, as _i j_.

A circumference is assumed to be divided into 360 equal parts, termed _degrees_. The degree is subdivided into sixty equal parts, or _minutes_, and the minute into 60 _seconds_. These are respectively symbolized by the marks ° ′ ″ placed at the right-hand top corner of the figure.

Such an expression as 18° 30′ 15.5″ would, then, be read 18 _degrees_, 30 _minutes_, and 15.5 _seconds_.

=11.= =Ratio of the circumference to the diameter.= The diameter of a circle is to the circumference as 7: 22; or, employing decimal fractions, as 1: 3.14159 (a number which, in algebra, is always represented by the Greek letter π.)

[Illustration: _Fig. 1._]

Knowing a diameter (D), the circumference, _x_, can be ascertained from the proportion:—

1 : 3.14159 :: D : _x_.

Knowing a circumference (C), the diameter, _x_, can be determined from the proportion:—

3.14159 : 1 :: C : _x_.

The latter proportion will also give the value of the radius, which is half a diameter.

=12.= The _superficial area of a circle_ is equal to the circumference multiplied by half the radius, or to the square of the radius multiplied by 3.14159.

A _sector_ is the circle enclosed between an arc and two radii bounding it, as _b_ O _r k_ (fig. 1.)

The area or surface of a sector can be ascertained by multiplying the length of the arc by half the radius.

A _segment_ of a circle is the portion intercepted between an arc and its chord, as _f d n_ (fig. 1.)

The surface of a segment, as _b k r s_, can be obtained by subtracting from the area of the sector O _b k r_, the area of the triangle, _b r_ O (=15=).

=13.= _Ring._ To determine the surface of a flat ring, the area of the inner circle must be subtracted from that of the outer circle; in other words, take the difference between the areas of the two circles that fix the inner and outer diameters of the ring.

The area of a flat ring can also be calculated by adding together the internal and external diameters; then multiply the number so obtained by their difference and by the decimal fraction 0.7854 (that is, 3.1415/4). The product will be the required area.

=14.= _Angles and their measurement._ When two lines meet one another, they form an angle, as we have already seen. If we take the apex as the center of a circle, the number of degrees intercepted between the two straight lines gives a measure of this angle.

The angle measured by a quarter of a circumference, or 90°, is termed a _right angle_.

An _obtuse_ angle is greater than a right angle, and an angle that is less is termed an _acute_ angle.

=15.= =Triangles, squares, etc., and their measurement.= The triangle or plane area enclosed within three straight lines joined two and two together (A, B, C, fig. 2,) is said to be _rectangular_ when one of its angles is a right angle; it is _equilateral_ when the three sides are equal, under which circumstances the three angles are also equal; and _isosceles_ when only two sides are of equal length.

The sum of the three angles of a triangle is always equal to two right angles. If only two of the angles are known, it is thus easy to determine the third.

Similar triangles are characterized by the fact that their homologous sides (that is, the sides opposite to equal angles) are proportional.

Peculiarity of the right-angled triangle. The square described on the longest side, termed the _hypothenuse_ (B, fig. 2,) is equal to the sum of the squares described on the two other sides. Hence, it follows that, if the lengths of the two shorter sides are known, that of the hypothenuse can be ascertained by extracting the square root of the number formed by adding together the squares formed on these two sides (=5=).

[Illustration: _Fig. 2._]

If the hypothenuse is known and one of the shorter sides, the third can be determined by extracting the square root of the number formed by subtracting the square of the known side from the square of the hypothenuse.

The _surface of a triangle_ is determined by multiplying one of the sides by half the perpendicular height of the angle opposite to this side.

=16.= The _surface of a square_ or of an oblong or _rectangle_ (_a b c d_, fig. 3) is equal to the product of the base multiplied by the height.

The sum of the squares described on the four sides is equal to twice the square described on a diagonal. This diagonal divides the rectangle into two equal rectangular triangles.

=17.= The _surface of a parallelogram or lozenge_, a plane figure with four sides, opposite pairs of which are parallel (_c f g d_ and _c i j d_, fig. 3,) is equal to the product of one side multiplied by the perpendicular height of the figure.

[Illustration: _Fig. 3._]

The sum of the squares described on the four sides of a parallelogram is equal to the sum of the squares described on the two diagonals.

=18.= =Measures of various solid bodies.= The volume of a cube of parallelopiped (that is, a body bounded by six four-sided figures, every opposite two of which are parallel) is obtained by multiplying the surface of the base by the height.

The _volume_ of a straight cylinder is the product of the surface of the circle which forms its base into the height of the cylinder.

The _area_ of the curved surface of a cylinder is obtained by multiplying the circumference of the circle forming its base by the height.

The _volume_ of a tube or cylindrical ring of rectangular section, such as the arbor-nut of a barrel, or the rim of a circular balance, etc., is equal to the product of the plane surface of its base (=13=) into its height.

The _volume_ of a _right cone_ or of a _regular pyramid_ is the product of the base into a third of the height.

The _surface_ of a _sphere_ may be determined by multiplying the square of the diameter by 3.1416 (=11=).

The _volume_ of a sphere is equal to this surface multiplied by a third of the radius.

GEOMETRICAL DRAWING.

=19.= An elementary knowledge of the art of drawing, an ability to represent the outlines of objects by simple lines, is of the first importance to the watchmaker.

Such a design is obtained by projecting on to one plane all the visible points of the object represented.

Projection on a vertical plane gives an _elevation_; the object is looked at from one side.

Projection on to a horizontal plane produces a _plan_; the object is observed from above, thus giving a bird’s-eye view.

The projection of a point on a vertical or horizontal plane is the foot of the perpendicular, from the given point on to the plane. Assume the line _n m_ (fig. 4), to be fixed in space; its horizontal projection will give _c d_, and its vertical projection, _r s_.

[Illustration: _Fig. 4._]

Miscellaneous details. When one portion of the object to be represented is found to pass behind other pieces so that it cannot be seen, the continuation is frequently indicated by dotted lines.

Surfaces that are situated in planes one behind the other are shaded, the more deeply according as they are farther back. This shading is produced by a number of parallel lines which may be vertical or horizontal.

Parts that are in relief are indicated by projected shadows, or by increasing the thickness of a line that would cast a shadow.

In order to distinguish the several shadings or to emphasize the lines by which they are separated, it is a very usual, though not invariable practice to assume the light to be coming from the left-hand upper corner.

When drawing a square in relief, such as _a b c d_ (fig. 3), the lines _c d b d_, will be made darkest; but if it is a recess, the lines _a b_, _a c_ should be brought into prominence by means of dark lines.

[Illustration: _Fig. 5._]

These several directions will be found useful when a hole, any cavity, a pin, a round object etc., has to be depicted, as in fig. 5. As a general rule, the thick lines should indicate the position at which a shadow would form, the light being assumed to fall on the drawing in the manner indicated above.

A _section_ shows a body as it would appear if cut in two, and one portion removed in order to expose the interior, as in fig. 6. A section is indicated by a series of parallel lines drawn close together and at an inclination of about 45° to the vertical.

[Illustration: _Fig. 6._]

In order to leave more room for important details, or to show objects that are situated behind, a piece is often broken off by an irregular line, as shown in that drawing.

Lines formed by a series of detached points sometimes serve as a means of associating several figures representing the same object looked as in different directions.

=20.= =Tracing and transfering.= These two operations are resorted to when it is required to obtain one or more copies of a picture or design already drawn.

Tracing consists in laying a piece of tissue or other translucent paper over the drawing and copying it by following over the lines that are visible with a pencil. Or ordinary paper can be used for the purpose, providing it is not too thick, if the picture be placed against the pane of a window or, what is more convenient, on a sheet of glass used as a desk and illuminated from below. When either sheet of paper is too thick to allow sufficient light to pass, one or other of the methods of transfering indicated below must be resorted to.

=21.= This operation consists in reproducing a tracing on a separate sheet of paper or on metal that is to be engraved. Either of the following methods may be adopted:

1. The picture to be transferred is fixed to a table or drawing board if tracing paper is to be used, or to a sheet of glass if only ordinary paper is available. The lines are then traced with a black lead pencil that must not be too hard. When this is finished it is laid, face downwards, on a sheet of white paper, taking care that both sheets are so fixed that they shall not slip. Apply pressure to the upper surface by tapping with a small pad made on purpose and, at the same time, gently rubbing. Experience will very soon show how hard the pad should be. Now remove the tracing, still taking care to avoid any slipping, and a faint reproduction of the design will be found on the lower sheet of paper. It is only necessary to follow over the lines with India ink. The figures will be reversed but a transfer with it in the original direction may be obtained by inverting the picture and laying it on glass so as to make a reverse tracing.

2. Lay the picture on a desk or drawing board and trace it with ink on a very transparent sheet of paper. When the ink is dry, invert the tracing and blacken the back with a No. 2 pencil. Now lay the tracing, with the ink side uppermost, on a sheet of clean paper,

taking care to avoid slipping, and go over the several lines with an agate or metal style, avoiding excessive pressure on account of the risk of tearing the paper. On removing the upper sheet an impression will be found not reversed. Go over all the lines with India ink and clean the paper with India-rubber or stale bread.

Observations. The choice of paper and pencil is not a matter of indifference. All kinds of paper do not receive an impression equally well, neither do all pencils transfer with equal facility. The Faber pencil No. 3, will generally be found best suited to such work.

In preparing drawings which you desire to preserve, as drawings of escapements, etc., a good quality of light weight bristol board will be found more desirable than the best drawing papers. White wedding bristol, about two-ply in thickness, answers admirably, and India ink lines drawn upon it will not spread as they often do on drawing papers. The prepared liquid India inks now on the market are superior to any you can prepare by grinding the sticks.

=22.= =To transfer an engraved design.= This method is available when it is desired to obtain an impression, for example, of the engraved surface of a watch case.

Procure some of the inks used by copper-plate engravers, or, in its absence, ordinary stencil ink may be used. Taking a small quantity on the end of the finger, tap it on the surface of a glass plate, in order that the ink may be distributed, leaving only a small quantity evenly spread over the finger: tap with the finger thus prepared over the watch case long enough to make sure that all the surface in relief has received some ink; take a piece of writing paper and, after slightly moistening it, spread it over this surface. Lay above this a piece of paper folded in four and pass over it in all directions any round body, such as a small tool handle, and with some pressure; then raise the papers without allowing them to slide.

If the operation has been carefully performed a very clear impression will thus be obtained of the engraved surface. The relief will be black and the hollows white, but, of course, the figure is reversed like that in a looking-glass. If required in the right direction it must be traced through to the other side of the paper.

DRAWING INSTRUMENTS.

=23.= It is needless here to describe the rule, set-square, =T=-square, bow-compass, etc., as every one knows them.

To verify the accuracy of a rule. On a perfectly flat smooth surface carefully draw, with the rule in question, a fine straight line. Then turn the rule over, hinging it as it were on the line just drawn; if quite straight the edge of the rule will exactly coincide with the line, in this new position, throughout its entire length. Each edge should be thus examined.

To verify the accuracy of a set-square. Having fixed an accurate rule on a smooth surface, place one edge of the set-square against it, and draw a line along the edge perpendicular to the rule; then, having turned the set-square, hinging it on the line just drawn, bring it against the rule and along the line. If the square is true the edge and line will coincide throughout their length.

=24.= =The Protractor.= Fig. 7 represents a common form of this instrument. It is made of horn, or, if of metal, the inner portion is cut away, leaving only a base and a semicircular arc, which is divided into 180 equal parts or degrees; a complete circle would therefore consist of 360 such degree. The point indicating the center of the arc, should be very small in order to facilitate the exact setting of it at the apex of an angle.

[Illustration: _Fig. 7._]

When an angle has to be drawn with accuracy, the protractor is unsuitable; it will be better to adopt one of the methods described at paragraph =37=, or trigonometrical methods.

=25.= =Drawing scales.= When an object is represented by a drawing, if the dimensions are the same as those of the object itself, or, rather, as they would project on to a horizontal or vertical plane, the drawing is said to be full size; but the object is generally represented either on an increased or diminished scale, which is defined, the proportions between all the parts being still, however, maintained the same.

With a view to avoid the many calculations that such a change would involve, it is usual to employ drawing scales. The following notes will sufficiently explain their construction and use.

Let it be required to reproduce a large drawing on a small scale, in such a proportion that the dimensions are reduced in the ratio of 10 to 1.

[Illustration: _Fig. 8._]

Take a straight line of indefinite length, _a b_, fig. 8, and mark out on it spaces equal to _a_ 1, which represents any measurement taken on the original object; at _c_, the 10th division, draw a perpendicular, and on it measure _c g_ equal to _a_ 1, or one-tenth of _a c_ and join _a g_.

Through the points indicating the divisions into tenths draw lines parallel to _c g_, and you will thus have a series of triangles, _d a_ 1, _d′ a_ 2, _d″ a_ 3, etc., similar to the triangle _g a c_. In virtue of a well-known property of such triangles (=15=), _d_ 1 will be one-tenth of _a_ 1; _d′_ 2 one-tenth of _a_ 2; and so on.

Thus, if a measurement taken on the object, or on a large drawing, is equal to _a x_, it will only be needful to turn the compass on the point _x_ as a center, and to observe accurately the perpendicular height, _x z_, to ascertain the corresponding measurement on the reduced scale.

Such a scale can be employed to measure meters and decimeters, or feet and inches (but in this latter case, it would have been necessary to mark off 12 instead of 10 divisions from _a_). Since _a_ 1 might be made to represent one metre; _a_ 2, two meters, etc., in virtue of the principle of the triangle already referred to, _d_ 1 will be the tenth of _a_ 1, and will therefore represent a decimeter; _d′_ 2 will represent 2 decimeters, etc. The length required to represent, say 5.3 will be ascertained by taking the distance _a_ 5, to which the distance _d″_ 3 is added. Similarly 6 feet 2 inches would be given by _a_ 6, to which _d′_ 2 is added on a 12-division scale.

=26.= The following description of one of these decimal scales, which is engraved on metal or ivory, and often included in cases of drawing instruments, will suffice to enable any one to construct a scale on this principle, that goes to a still further degree of accuracy, measuring, for example, meters, decimeters and millimeters, or yards, feet and inches.

[Illustration: _Fig. 9._]

Let A B, fig. 9, be a flat rectangular rule, divided throughout its length by parallel equidistant lines into ten strips. At right angles to these are the lines _o o′_, _a a′_, etc., separated from one another by a distance of one centimeter (doubled in the drawing in order to make the details more clear.) The first centimeter is subdivided along the two edges, A _o_, _n′ o_, into 10 equal parts or millimeters, and the division, _o_, on the upper edge is joined by an oblique line with the 1 on the lower edge, and the others by parallel oblique lines as shown in the figure. Thus _c i_ will be one-tenth of a millimeter, _s j_ two-tenths, and so on.

If the compass is opened so as to reach from _x_ to _z_, it will be seen that it covers a space of 16 millimeters and 2-10ths of a millimeter, for there are one large division (or 10 mm.), 6 smaller divisions (or millimeters) plus a fraction of a millimeter equal to _s j_ or 2-10ths of a millimeter.

=27.= =Sector.= When it is required to reduce the scale of a drawing, subject to the condition that the dimensions shall be all diminished in the ratio of two given lines, we may state the problem thus:

The longer of the two given lines is to the shorter, as any given dimensions of the old drawing is to _x_. The value of _x_ thus determined will be the corresponding dimension of the new figure.

Such a rule of three proposition would involve a considerable amount of work, and the required result can be arrived at with greater facility by the geometrical methods which forms the basis of the scale just described, or, better still, by using the sector shown in fig. 10. It consists of two brass or ivory legs hinged about a center _m_ which is at the apex of the angle _n m c_ formed by two straight lines similarly divided into equal parts.

[Illustration: _Fig. 10._]

It is employed as follows: Let us assume that a drawing has to be reduced in the ratio of the line A to the line B; set off the length A along _m n_, and suppose its extremity to be at _s_, where division number 5 occurs. Open a compass to a distance equal to B, and placing one point on _s_, open the two legs of the scale until the second point coincides exactly with the corresponding division _t_, that is, with the 5 on the other leg, _m c_. Maintaining the scale open to this amount, it is only needful, after measuring a

distance on the original drawing or object, to set it off along _m n_, and to measure the distance between its extremity and the corresponding point on the other leg; this distance will be the dimension on the reduced scale.

=28.= =Proportional compass.= This consists of two equal stems terminating with points, fig. 11. They are cut through for a portion of their length, and provided with a slide forming a hinge, that can be clamped by a screw _a_ in any position. Graduations on the two slots and a mark on the slide indicate in what position of the slide _a_, the length _a b_ (equal to _a g_) is equal to ½, ■, ¼, etc., of _a d_; and thus show what is the ratio of _g b_ to _c d_, a ratio which is independent of the extent to which the arms are opened.

[Illustration: _Fig. 11._]

=29.= =The vernier.= The vernier consists of a small graduated slide which is adapted to a graduated rule or circular arc with a view to ascertain the value of small fractional parts of the divisions marked on the rule or arc.

Let A B, in fig. 12, be a rule divided into millimeters (the proportions are enlarged in the drawing so as to avoid confusion among the lines), and let it be required to determine a length to within the tenth of a millimeter.

As the measurement is required to the tenth, take ten less one or nine of the divisions of the scale; they will extend from O to IX, and this represents the acting length of the vernier.

Subdivide the vernier into ten equal parts; it is manifest that each graduation of the vernier differs from the original subdivisions of the rule by 1-10th of a graduation of the latter. In other words, unity on the vernier is equal to 9-10ths of unity on the rule.

[Illustration: _Fig. 12._]

When the rule and vernier are placed as shown in fig. 12, so that the o on both scales coincide, the successive divisions on the rule (marked with Roman numerals for distinction) will be progressively more and more in advance of the corresponding divisions on the vernier in the following proportion:—

The marks I and 1 are 1-10th apart; the marks II and 2, 2-10ths; III and 3, 3-10ths; and so on, the mark X being 10-10ths, or one complete division in advance of 10, this division being a unit on the scale.

Thus if the vernier is caused to slide along the edge of the rule, when 1 coincides with I the vernier has advanced 1-10th; when 2 coincides with II, it has advanced 2-10ths; and so on.

Let it be required to determine the distance P _d_, fig. 13. The division 6 on the vernier coincides with a division of the scale; hence it follows that the extremity _d_ of the vernier is at a distance of 6-10ths millimeters from III, the next division of the scale to the left. The distance between P and _d_ is thus 3.6 millimeters.

[Illustration: _Fig. 13._]

With a vernier showing tenths, if two consecutive divisions of the vernier fall between two divisions on the rule, and there does not appear to be a tendency towards one side more than towards another, even when observed with a strong glass, it is possible to take an approximate reading to the twentieth.

[Illustration: _Fig. 14._]

In measuring circular arcs a curved vernier is used in place of a straight one, and its graduations are made to correspond with those on the circle as shown in fig. 14.

=30.= =Micrometer screw.= By employing a micrometer screw it is possible to measure infinitesimal amounts, but the screw must be perfectly accurate, and must work without appreciable backlash or loss of time.

[Illustration: _Fig. 15._]

Assume V, fig. 15, to be such a screw, having a pitch of 1 millimeter. It will advance by this amount with each complete rotation.

To the head of the screw is attached a disc of such a size that its rim can be divided into a number of equal parts, say a hundred. These graduations may be marks on the edge or notches cut in it when an index is required to stop in them; but the index is less

frequently met with than a simple divided straight-edge almost in contact with the disc. The divisions round the disc are numbered in ascending order as the points _c_ and _a_ separate, so that zero comes under the index or rule when these points are in contact. Readings of the numbers will thus afford a measure of the displacement of the point of the screw.

When the disc is rotated the point a will move towards or from _c_ by 1-100th of a millimeter for each division passing under the straight-edge, and one millimeter for each complete rotation. It is thus possible to obtain the dimensions of an object when it enters without play between the two jaws to within an error of about 1-100th of a millimeter if the instrument is accurately made.

If, instead of passing the object between the two jaws, it is gripped by them, the measurement will be less exact, as no account is taken of the pressure exerted and of the elasticity. (=44.=)

GEOMETRICAL DRAWINGS.

=31.= =Sketches.= It is advisable from an early age to accustom oneself to make rapid freehand sketches of objects as they present themselves to the eye. Such a sketch will help in the preparation of a more exact drawing, which involves a knowledge of the several geometrical methods given below.

A drawing may be transferred, reduced or enlarged as follows:

Draw across the original picture a number of equidistant vertical and horizontal lines, forming perfect squares, and number the two sets of lines in succession. Then draw a similar series of lines on a clean sheet of paper, setting the lines at an equal, less or greater distance apart, and copy in succession the parts of the figure that are enclosed within the several squares.

As it is not always possible to draw lines across a figure, they may be replaced by a frame carrying fine threads or wires stretched in the two directions. The frame is laid over the original drawing, which can then be copied, as above explained, on a sheet of paper divided into squares (fig. 16).

[Illustration: _Fig. 16._]

The frame may, moreover, afford assistance in the drawing of solid objects. Having placed it above or in front of the object and in contact with it, copy on to the sectional paper the contents of each corresponding square, taking care to look at the object perpendicularly. With a little practice, and by placing the eye in the correct position and always at the same distance from the frame (a distance which may be regulated by a glass), a sketch in fair proportion may easily be obtained.

[Illustration: _Fig. 17._]

=32.= =To erect a perpendicular on a straight line.= Either the compass or a set-square can be employed; the use of the latter instrument is so simple that no further reference need be made to it. Assume _a_, fig. 17, to be the point in the line _n m_ at which a perpendicular is to be drawn. On either side of _a_ measure off equal distances _a n_, _a m_; from _n_ and _m_, with a radius about equal to the distance _n m_, draw two circular arcs cutting one another. If their point of intersection _b_ be joined to _a_, the line _a b_ will be the required perpendicular.

[Illustration: _Fig. 18._]

=33.= =To erect a perpendicular at the extremity of a line.= From the extremity _c_, fig. 18, mark off four equal parts towards _s_. From _s_, with a radius equal to five such parts, describe a circular arc, and from _c_, with a radius of three such parts, describe another arc cutting the first at _d_. The line joining _c_ and _d_ will be perpendicular to _s c_.

For the square of 5 is 25, and this is equal to the square of 4 or 16 plus the square of 3 or 9. Thus the triangle _s c d_ must be right-angled (=15=).

[Illustration: _Fig. 19._]

Or the following method may be adopted: With any center _i_ and radius _i g_ (fig. 19), as large as possible, describe a circumference passing through _g_. From the point _p_, where the circle cuts the line, draw the diameter _p i h_. If the point _h_ be joined to _g_, it is the required perpendicular; for, by a property of the semicircle, the angle _h g p_ is a right angle.

[Illustration: _Fig. 20._]

=34.= =To let fall a perpendicular on a straight line.= In order to let fall a perpendicular from the point _a_ on to the line _b c_ (fig. 20), describe from _a_ as a center, a circular arc sufficiently large, cutting the straight line in two points, _b_ and _c_. From these two points, with the same opening of the compass, draw on the under side of the line two arcs that intersect. The point of intersection _o_ joined to _a_ gives the required perpendicular.

[Illustration: _Fig. 21._]

=35.= =To draw parallel straight lines.= Having fixed a good straight-edge over the drawing, as many parallel lines as are required may be drawn with the aid of a set-square which is caused to slide along the rule. They will be vertical, horizontal or inclined, according to the position of the rule, which must be set exactly perpendicular to the direction in which the parallel lines are to be drawn (fig. 21).

[Illustration: _Fig. 22._]

To draw, from a given point, a line parallel to a given line. Let _d_ be the given point, and _a b_ the given line (fig. 22). From _d_ draw the circular arc _a c_, and from _a_ where it cuts _a b_, with the same radius describe the arc _d b_. From _a_ set off on _a c_, a distance equal to _d b_. The line joining _d_ and _c_ is the required parallel.

[Illustration: _Fig. 23._]

=36.= =To subdivide a line into equal parts.= Let it be required to divide the line _p v_ (fig. 23), into five equal parts. Draw a line _p q_ inclined at any angle, and mark off on this line five equal parts of any length; join _q_, the extremity of the five lengths, and _v_, and through the points _a_, _b_, _c_, _d_, draw lines parallel to _q v_. In virtue of a property of similar triangles these lines will divide _p v_ into equal parts. It is advisable that the lines _p v_ and _p q_ should not differ very considerably in length, as, otherwise the inclination of the parallel lines to _p q_ will render it difficult to observe the exact point of intersection.

[Illustration: _Fig. 24._]

To divide a line into proportional parts. The proposition can be solved in a similar manner. Let it be required to divide a line _t r_ (fig. 24), into two sections that are to one another in the proportion of 5 to 3. On _t s_ mark off a series of equal parts given by the addition of these numbers together, that is 8; and join the last point _s_ to _r_. Then draw through _c_, the fifth division, a line parallel to _s r_. This line _c d_ will cut _t r_ into two parts, which are to one another in the proportion of 5 to 3.

By an analogous construction a fourth proportional can be graphically obtained, as already indicated in articles =25=-=27=.

=37.= =To construct an angle equal to a given angle.= The angle may be measured by means of the protractor (=24=), which then enables us to draw a similar angle; but greater accuracy is obtainable by using the compass.

[Illustration: _Fig. 25._]

Let it be required to construct at _m_ on the line _m p_ (fig. 25), an angle equal to _b a d_. With as large a radius as possible, draw from the points _a_ and _m_ the arcs _b d_ and _n p_. Measure the distance _d b_ and mark it off with the compass from _p_ on the arc _p n_. A line drawn through _m_ to the intersection of the two arcs will give the required angle equal to _b a d_.

=38.= =To subdivide an angle into 2, 4, or 8 equal parts.= In addition to the use of the protractor, the following graphic method is often given in works on geometry.

[Illustration: _Fig. 26._]

An angle _e f g_ being given (fig. 26), from its apex _f_ as a center describe the arc _e g_, and from its two points of intersection with the sides, with a radius greater than half their distance apart, draw two short arcs cutting each other at _s_. A line drawn from _f_ through the intersection _s_ will divide the angle into two equal parts.

If four divisions are needed, repeat the process on the two angles _s f e_, _s f g_, and so on for a further sub-division.

The line that divides the angle into two equal parts will also bisect or divide into two equal parts the chord and the arc _e g_.

[Illustration: _Fig. 27._]

=39.= =To find the center of a circle or of a circular arc.= Take on the circumference, or on the arc, three points _b c r_ (fig. 27). Join _b_ to _c_ and _c_ to _r_. At the middle point of each of these lines[3] erect a perpendicular. The point of intersection of these perpendiculars is the required center.

A similar method should be resorted to when it is desired to describe a circle passing through three given points.

[Illustration: _Fig. 28._]

=40.= =To connect up or associate lines.= In order to join up a straight line, such as _i j_ (fig. 28), with the curve _l p_, erect a perpendicular at _j_, and through the middle point of a chord, _l p_, draw a second perpendicular cutting the first in _k_. This point will be the center from which the curve uniting the two lines should be struck.

[Illustration: _Fig. 29._]

To unite a curve _a b_ (fig. 29), with another curve, _c x_ or _c z_, at the point _c_, first find _o_, the center of the curve _a b_, draw the line _a o_, continuing it beyond the center; join _a_ and _c_, and erect a perpendicular at the middle point of this chord. The intersection of this perpendicular with _a o_, produced if necessary, should be taken as the center for a curve uniting _b a_ with _c_.

[Illustration: _Fig. 30._]

To join up two lines inclined to each other or parallel lines of unequal length, such as _a r_, _b s_, fig. 30, draw midway between the two another line, _z d_; join the two extremities _r_ and _s_, and from these points let fall perpendiculars _r i_ and _s c_; then from _d_ draw a line perpendicular to _s r_. The point _o_ thus obtained will be the center of the arc _r d_, and _c_ will be the center for _d s_.

=41.= =To describe an ellipse.= Let _a b_ (fig. 31), be the major axis of the ellipse; divide it into three equal parts, and from the two points, _c_ and _i_, at which it is divided, with a radius equal to _i c_, draw (in pencil) two circles, intersecting in the points _x_ and _z_. Through these points draw the lines _x i g_, _x c h_, _z i f_, _z c d_.

With the center _z_ describe the arc _d f_, and from _x_ draw _h g_; the ellipse will be completed by the two arcs, _f b g_, _d a h_, of the primitive circles.

[Illustration: _Fig. 31._]

If it be required to describe an ellipse that shall have a shorter minor axis, divide the major axis into four equal parts, thus obtaining three points of sub-division. With each point as a center and with a radius equal to one of the spaces describe circles. Those to the right and left will determine the extremities of the ellipse, and the central circle will intersect the minor axis in two points which must be taken as centers for describing the top and bottom portions of the figure.

[Illustration: _Fig. 32._]

When the length of the long and short axes are given, proceed as follows (fig. 32): From the center _a_, where they intersect at right angles, mark off the distances _a n_, _a o_, equal to the difference in the length of two semi-axes. Join _n o_, and add one half of _n o_ to _a o_ measured in the direction of _a v_, thus obtaining the point _k_; with the radius _a k_ describe a circle. On this circumference will lie the four centers; _k_ for the arc _r u s_, _m_ for the arc _p v q_, _t_ and _i_ for the short arcs _q j s_, _p e r_.

The figures obtained by the methods here given closely resemble the ellipse, but are not of the strict mathematical form. It is well to acquire some facility in drawing ellipses, for the projection of a circle on a plane, when the two are neither parallel nor perpendicular, is an ellipse, and one often has occasion to describe it.

=42.= The following may be added as a mode of describing an ellipse:

The major axis and the two foci (points in this axis) being known, fix two pins in these foci. Then tie a piece of string into a loop and place it over the pins; stretch it with a pencil, the point of which is on the paper, and on moving this around in a circular direction, the string being maintained stretched, an ellipse will be described. When the string is so stretched that it lies along the major axis, the length should be such that the pencil is exactly at its end.

[Illustration: _Fig. 33._]

=43.= =To draw a spiral curve.= Draw four lines forming a small square (fig. 33). The point _o_ is taken as the center of the first arc, _i j_; _s_ is the center of _j k_; _u_ of _k l_; _i_ of _l n_. Then, to continue the curve, _o_ is again taken as the center for _n p_, and so on. This method produces a volute in which the coils are at a considerable distance apart, such as has no special applicability to horology.

[Illustration: _Fig. 34._]

As the balance-spring of a watch is partially concealed by other pieces, it is generally sufficient to represent the parts that show themselves by concentric circular arcs, or arcs described from two centers. If a more accurate representation be required, the following method may be resorted to: when working on a small scale it involves the use of the eyeglass, for the figure (fig. 34,) here given is exaggerated in order to avoid confusion in the lines, numbers, letters, etc.

A small circle having been described, it is divided into an even number of equal parts, say four; a less number than this should never be adopted. From the same center describe another circle as small as possible, which will be cut by the two diameters drawn between opposite points of division numbered 1, 2, 3, 4.

Assuming _a_ to represent the starting-point of the curve, from the center 1 with radius 1 _a_ draw the arc _a b_; from 2 with radius 2 _b_ draw the arc _b c_; from 3 with 3 _c_ draw _c d_; from 4 with 4 _d_ draw _d s_; then recommencing with 1 and the radius 1 _s_ draw _s f_, and so on.

The less the radius of the small circle and the greater its number of divisions, the closer will the successive coils be together. To secure accuracy when working on a small scale, it is advisable that the center and the several points be in a thin brass or horn plate, which is maintained in position by steady pins.

THE MICROMETRICAL DIVIDING TABLE.

=44.= This instrument is no more than a simple application of the screw to dividing straight lines, but it will suffice to enable the reader to understand the principles on which the more complicated instruments are based.

[Illustration: _Fig. 35._]

A plate, P, fig. 35, supports a bracket _a_, in which a screw, similar to the one described in paragraph =30=, is engaged by means of a collet; it rotates, being supported between this bracket and the small bearing _b_, that receives the pivot at the end of the screw.

The screw is fitted carefully into a nut _n_, which is rigidly attached to the small plate _h_; this carries a fine marker, movable on an axis, and terminating with a chisel edge or a fine diamond point, according as the instrument is to be used for engraving metal or glass; or it may be provided with a fine pencil if the object is merely to make subdivisions on a drawing.

This being understood, it will be evident that, if a rule or rod of any form be fixed by screws or otherwise between _f_ and _g_, it can be graduated by means of the marker, the screw being made to advance; the millimeter screw can be used for dividing into millimeters and fractions direct, or, with a little calculation, into fractions of an inch. Each complete rotation of the head means a displacement of the marker by a millimeter; a half turn will be half a millimeter, etc.

OTHER METHODS OF DIVIDING INTO EQUAL PARTS.

[Illustration: _Fig. 36._]

=45.= =First method.= Having fixed a sheet of drawing paper on a smooth board, draw the line M N, fig. 36, longer than the rule which is required to be divided. Then, with a compass or graduated scale, mark off a series of equidistant points, commencing at N, equal in number to the required series on the rule, and let M be the last division. With the center N and radius N M describe the circular arc _p v_, and with M as a center and the same radius, describe a second arc _r s_, intersecting the first at O. Join O with M and N. Assume _a c_ to be the rule that is to be divided into equal parts; slide it on the paper parallel to M N until the extremities, _a_ and _c_, coincide with the lines O M, O N, and are equidistant from O. This position can be easily found by the aid of a compass with one of its centers at O. Now fix the rule in position with sealing-wax, or by some other means, and, with a firm upright

pin, center the brass rule R at O, so that it can rotate round this center on the pin as a pivot. It now only remains to trace a series of lines O _k_, O _b_, O _d_, etc., with the rule, to the division points of the line M N. The line _a c_ is thus divided into as many equal parts as the line M N. The graduations will be all the more exact according as the divisions of the line M N are longer.

=46.= =Second method.= By the side of the chuck of a wheel-cutting engine, arrange a horizontal slide _y f_ fig. 37, that can travel easily in a direction perpendicular to _a_ T. A watch fusee-chain, or a very flexible spring, is fixed by one end to the chuck, and by the other to the slide at _d_. The chain or spring is kept stretched by a weight which tends to draw the slide from _f_ towards _d_.

[Illustration: _Fig. 37._]

The rule to be graduated, _a_, is now fixed on the slide, and an initial division is marked on it with a pointed rotating cutter in the position usually occupied by the wheel cutter, or else by striking a small pointed or flat-edged chisel arranged for the purpose, in such a manner as not to be liable to derangement.

Rotate the table through a definite distance; the rule _a_ will advance through the same distance; mark the second division; then having moved the division-plate through a distance equal to its first displacement, mark the third graduation, and so on. Suppose, for example, that it be required to make 30 divisions on the rule between _f_ and _d_; select on the plate the circle corresponding to twice or thrice this amount, so that the radius of the chuck may not be relatively too short, and that the chain or spring may not act at a disadvantage; take the number 60 for example:

The two marks at _d_ and _g_ on the spring indicate the length that corresponds to the straight line to be divided.

The chuck is placed in the lathe and reduced in diameter until the half circumference is exactly equal to the distance between these two marks on the spring, which thus fall on a diameter, _i g_, of the chuck.

The spring having been fixed by its two extremities, the slide with the rule attached is placed in position, so that the mark _g_ is on the line _a_ T; it will be evident from the figure that each displacement of the division-plate through one-sixtieth of its circumference will cause _a_ to advance through one-thirtieth of the space between _f_ and _d_.

Remarks.—Knowing the relation of a diameter to the circumference (as 1 : 3.1416), we can determine the diameter of the chuck at once by calculation.

Its form should be a true cylinder, and it is well to place guides that will prevent the spring or chain from assuming a helical position.

The side that carries the rule should be strictly perpendicular to _a_ T; and the portion of the spring that is not coiled on the chuck should always be parallel to this slide.

The chuck and spring must be quite clean and smooth, and the latter should be very pliable. A greater weight will be needed to keep the spring stretched than will suffice for a chain, and it must be increased as the strength of springs is greater.

The slide, _y f_, may simply travel over a horizontal surface between pins planted in two parallel lines. But it would be preferable to adopt some other method, for instance, to make this piece (F, fig. 37), travel with a little friction along a perfectly true cylindrical rod.

=47.= =Third method.= This is merely an application of the arrangement mentioned in paragraph =44=. The lathe can be employed for marking off a series of equidistant points in a straight line. Knowing the pitch of the slide-rest screw, determine the distance apart in, say, millimetres, of the required divisions, and fix the rule perfectly flat on the face-plate, which must be rendered immovable by any convenient means. Then mark the first point with the drill-stock. Advance the screw by the amount previously determined upon and mark the second point. After withdrawing the drill, again advance by the same amount and mark the third point, etc. Always be careful, before making the first mark, that the screw has already traveled some distance in the direction it will continue to move, so as to avoid backlash, or loss of time.

TO SUBDIVIDE A CIRCLE.

=48.= =To divide the circumference into equal parts.= After having drawn the circle, A, fig. 38, draw two diameters, _d a_, _b c_, at right angles to each other, dividing the circle into four equal parts. Join the points, _c a_, and divide the line, _c a_, accurately into nine equal parts.

Draw a series of circles concentric with the first, at distances apart equal to one of the divisions of _c a_, and to the number of one, two, three, etc., according as it is required to subdivide the circle, say for a pinion, into seven, eight, nine, etc., equal parts.

[Illustration: _Fig. 38._]

With a fine-pointed compass, measure off the radius of the initial circle A. Placing one point of the compass at _c_, the other point will give the position of the next leaf, and so on, all around the circumference. If the innermost circle A be selected for sub-division, six divisions will be obtained, and there will be one more division for each larger circle.

The operation will be facilitated by selecting the first circle, so that the line _a c_ contains exactly nine divisions equal to those of some scale that is accessible. Such a circle can be easily found, by first drawing the two diameters, laying the scale in the direction _c a_, and determining by trial the radius for which the first and ninth divisions correspond to _a_ and _c_ respectively.

=49.= =To divide a surface into rings of equal or proportional superficial area.= The following solution is due to M. Brocot:

Let _a d_ be the radius of a circle (fig 39), that is required to be subdivided into four rings of equal area by concentric circles. Taking _a d_ as a diameter, draw the semicircumference, _a b d_; accurately divide _a d_ into four equal parts, and at each point so obtained, erect a perpendicular. Through the intersections of these perpendiculars with the semicircle, draw a series of concentric circles; they will trace out rings, 1, 2, 3, 4, that have equal superficial areas.

If it be required to divide the surface in a given proportion, divide the line _a d_, according to that proportion.

[Illustration: _Fig. 39._]

The right-hand side of fig. 39 gives a special application of this method to the division into two equal areas of the interior of a barrel exclusive of the space occupied by the arbor-nut. If the mainspring accurately covers _i c_ when wound up, and _i j_ when unwound, it will give the greatest possible number of turns.

TIME.

=50.= Solar time is taken from the revolutions of the earth, and the watchmaker can easily get the exact solar time of any point at which he may happen to be by a little calculation from known standards. These standards are: 1. The zenith. 2. The longitude of the point of observation. 3. The difference between noon at the point of observation and noon of a known meridian either east or west of the point of observation. The zenith is that point in the heavens where the rays of the sun are in a plane exactly perpendicular to the surface of the earth at the point of observation, and when the rays of sunlight are in this plane it is noon at that point. The circumference of the earth is divided into 360 degrees or meridians of longitude, so that as the earth revolves once every twenty-four hours, each of these meridians will pass the zenith, or fixed point, in that time. In twenty-four hours there are 24 × 60 = 1,440 minutes, so that the interval between the passage of one meridian and the next will be 1,440 ÷ 360 = 4 minutes. A degree of longitude is divided like an hour, into minutes and seconds, so that

1 degree of longitude equals 4 minutes of time. 1 minute ” ” ” 4 seconds ” ” 1 second ” ” ” ½■■ or .066 seconds of time.

=51.= Thus it happens that, at a town one degree east of a given point the sun will be visible four minutes sooner, and if to the west, four minutes later than at that point. The “local,” or solar time, therefore, will be four minutes earlier at the first town, and four minutes later at the second town, than it is at the point of observation.

=52.= It will be readily seen that, having any two of the three factors given above, the other can be readily found. Thus having the time of a given meridian and the local noon or meridian time, the longitude can be readily found; or, having the longitude (which can be readily obtained from a surveyor) and the time of a given meridian, “noon,” can be calculated, etc. The first method is followed in calculating distances at sea; the chronometer keeping Greenwich time, and the local noon giving the longitude.

When great accuracy is necessary, however, a fixed star is used as a means of observing the exact time when a revolution of the earth is completed, as the revolution of the sun in its orbit causes a slight variation during the year. For further information on this point the reader is referred to works on astronomy.

To obviate the constantly varying time in running east or west, the railroads use the time of a given meridian over each fifteen degrees of longitude, and as each degree of longitude equals four minutes of time, it follows that only the hour is changed in

changing from one standard to another. In Europe the zero of longitude, or the time of the meridian of Greenwich is used. In the United States the time of the 75th degree, which passes through Philadelphia, is used from the 67th to the 80th degree, which comprises the territory from Princeton, Maine, to a line drawn north and south, passing through Erie and Pittsburg, Pa., and is called Eastern time. The time of the 90th meridian is used from the 80th to the 102d meridian, and is called Central time. The time of the 105th meridian is used from the 102d to the 114th meridian, and is called Mountain time. The time of the 120th meridian is used from the 114th meridian to the coast (which ends at about the 124th meridian) and is called Pacific time. The time of the various standards is telegraphed through their various territories at noon each day, and furnishes an accurate standard of comparison to all watchmakers.

=53.= In very many cities the actual or solar noon has been discarded and the railway standard adopted, thus making but one standard and removing the source of confusion and annoyance to many people. In others, however, the two standards are still used, and it becomes necessary for the watchmaker to be able to calculate both standards, in case of accident or irregularity in his regulator. Hence he should calculate his longitude within one second by means of the difference between railroad and local noon, and have the nearest surveyor correct his reckoning; then, by means of the accurate longitude and the railroad time, correct the solar time; then by means of the solar noon and the longitude calculate the railroad time. When all these calculations check each other perfectly, he possesses all the time data he needs for that place, and can correct his standard or regulator if at any time it should become irregular. The calculations are very simple, and can be easily performed from the data given above.

PART II.

MATERIALS EMPLOYED IN HOROLOGY.

IRON.

=54.= Iron is an elementary body, that is to say it cannot be decomposed. It is the most tenacious of the metals, having a breaking strain of about 75 kilo. per sq. mm. (or 106,000 pounds per sq. inch) of section. Two pieces can be perfectly welded together when raised to a white heat.

In the smaller horological appliances, the metal is not employed except after conversion into steel. In common clocks it is used from motives of economy, for forming pins, screws, etc. In turret clocks, however, considerable use is made of it, many of the parts after they are formed being cemented, that is to say, having their surface rendered hard in a manner subsequently indicated (=65=).

Such a mode of manufacture is particularly applicable to pieces that are subject to a constant succession of impacts; their hardened, steelified surface resists wear, while the iron core affords security against rupture.

It is important to carefully distinguish the cases in which iron is preferable from those in which its substitution for steel serves merely to augment the profits of the manufacturer.

The fracture of a good piece of iron is characterized by long twisted fibres of a brilliant white color.

If heated frequently or carelessly, the quality of the metal is impaired—it ceases to be fibrous and looses its tenacity: in this condition it is said to be _burnt_.

It is better to work with a charcoal or gas fire, as coal acts more rapidly in rendering the metal brittle. Cold hammering, or “hammer-hardening,” also makes it brittle and diminishes its tenacity, but this is again restored by a suitable annealing.

Iron dissolves slowly in dilute nitric acid; if not diluted, this acid rapidly oxidizes it. Dilute sulphuric acid dissolves the metal easily, but if concentrated, it has no action in the cold, whereas, on heating to ebullition, the iron is dissolved with evolution of sulphurous acid gas. It is also dissolved by hydrochloric acid, or aqua regia.

Iron is less magnetic than steel, especially hardened steel, which, owing to its great coercive force, is magnetized with greater difficulty, but retains its magnetism for a longer period. Indeed, _soft iron_, if properly prepared, can be magnetized and demagnetized instantaneously.

Some workmen can distinguish iron from steel by the musical note emitted on striking. A more certain method, however, consists in using dilute nitric, or sulphuric acid. If the surface remains unaltered, or nearly so, when touched with a drop of either acid, the metal is iron, but, in the case of steel, a black mark will be left, owing to the liberation of carbon.

=55.= =To Remove Rust.= The usual mode is to rub the object with a piece of oiled rag, or emery paper. It appears that more rapid and more satisfactory results are secured by using very pure petroleum, and wiping with a hempen or woolen rag.

=56.= =To Prevent Rust.= Dip iron or steel articles in a mixture of equal parts of carbolic acid and olive oil, rubbing the surface with a rag. Others rub the metal with a mercurial ointment, leaving a thin layer over the entire surface. It is stated that, if iron be dipped in a solution of carbonate of potash or soda in water, the surface will be protected against rust for a long time, and objects can be protected for any period by burying in quicklime. Rubbing the surface with plumbago has a similar effect, and Barff has pointed out that, by exposing iron to the action of steam, heated above the boiling point of water, a coating of magnetic oxide of iron is formed, which is equally serviceable.

=57.= =To restore iron and steel that has been burnt, or badly forged.= When iron is burnt, or carelessly forged, it becomes crystalline and brittle; in order to restore it to its original condition, a fresh and very careful forging is generally needed. This can be avoided by having recourse to the following method, suggested by Caron: it consists in treating the metal somewhat after the manner adopted in hardening steel.

He experimented with a bar of good iron, which was easily bent when cold, without breaking or showing any cracks. It was then burnt and became brittle when cold, the fractured surface showing brilliant shining facets.

Prepare a boiling saturated solution of sea-salt, heat the piece of iron to a bright redness, and plunge it into the bath until it is of the same temperature (about 110° C. or 230° F.) After undergoing this operation, it is found that the metal can be easily doubled in the cold, exactly as it did before being burnt.

Perret states that steel which has been deteriorated by frequent hardening can be restored as follows: Heat it short of dull redness and quench in melted tallow, repeating the operation, if necessary, when the steel may be again hardened in the ordinary manner, and will be nearly, if not quite, restored to its original condition.

CAST IRON.

=58.= This is only used in the manufacture of tools and large clocks; the employment of cast iron wheels in the striking train of such clocks has materially reduced their price.

Like steel, it is a compound body, consisting mainly of iron and carbon. Cast iron, however, differs from steel in the quantity of carbon present, for, whereas its proportion in cast iron varies from 2 per cent. upwards, there is never, in steel, an amount exceeding 1.5 per cent., and even .5 per cent. renders an iron hard, converting it into “mild” steel.

Cheapness is not the only argument in favor of the use of cast iron. In virtue of its molecular structure, this material offers a considerable resistance to a crushing strain, so that the teeth of wheels, made of carefully selected cast iron, will work for a long time without sensible wear; moreover, the founder’s art has made such important advances that there is no difficulty in casting, to a constant pattern, a wheel, together with the pinion that it carries, and any other projections, etc., that may be required; this economizes labor to a very great extent.

The use of cast iron in the construction of certain classes of wheels, and parts of tools, presents advantages which we cannot afford to ignore; but it must be carefully observed that this material is not suitable in cases where great accuracy in the acting parts is required, as it cannot, like brass and steel, be conveniently worked by the turning tool or file. In recent years, however, this difficulty has been overcome by the introduction of what are termed “malleable castings,” produced as follows:

=59.= =Malleable Castings.= The object is first made of ordinary cast iron, and the invention consists in rendering this malleable by the removal of the carbon that has served the very important purpose of rendering the metal fusible. In large cast iron pots, the castings are laid with alternating layers of powdered red hæmatite, and the whole is kept at a temperature of about 900° C. (1,650° F.), or cherry-red heat, for 72 hours. On cooling, the castings are found to consist of nearly pure iron, and to be perfectly malleable, and, therefore, workable.

STEEL.

=60.= The treatment of steel involves some of the most prolonged and delicate operations in the entire range of horology. If the metal is badly selected and prepared, the working of it will be laborious, difficult and unsatisfactory; the resulting object will be distorted in the hardening, and will not harden uniformly; in short, it will occasion much toil and loss of time, with very little success.

Let the young watchmaker accustom himself from the first to study the steel that he uses, so that he may be thoroughly cognizant of both its advantages and defects; he will, in the practice of his art, be amply repaid for the brief time spent in making such an examination.

=61.= Steel is not an elementary body; it is usually regarded as a carbide of iron, that is to say a combination of carbon and iron. Analysis, however, proves other substances to be usually present in almost infinitesimal quantities; their remarkable influence on the physical properties of the metal has not yet been fully investigated, but much attention is being devoted to them at the present day.

The varieties of steel are very great. What are known as _puddled_ and _natural_ steel are obtained by acting directly on cast iron. _Cementation_ is a very old method of converting bars of malleable or pure iron into steel by enclosing them in charcoal and heating the whole for several days, until the carbon has worked itself into the center of the bars in such quantity as to covert the iron into steel.

The steel obtained by the above method is very heterogeneous; in other words, the composition is not uniform throughout a given block or bar. One part is highly carbonized, whereas another part, especially towards the center, will not be sufficiently so. The _grain_, although very fine in one part, will be more coarse in another; hard particles of pure cast iron, termed “pins,” are to be met with that resist the action of the graver or the file and give rise to cracks in the hardening, hammering, etc., and portions or sometimes even entire layers that have taken up no carbon whatever. The differences in the density, hardness, malleability, etc., that can be shown to exist at different points in the same bar arise from this cause.

Such faults can in part be corrected by _shearing_, an operation which consists in binding together a number of bars in a bundle, raising them to a red heat and beating them with sledge or steam hammers so as to weld them into one. The bar thus obtained is again heated, folded several times on itself, again hammered, rolled, etc., when it is termed _shear steel_. If these operations are performed carefully and without a too great heat, the quality of the steel is much improved; it is more homogeneous and can be worked with greater facility.

=62.= The discovery of the earliest method of producing _cast_ steel, thoroughly homogeneous, was made by a watchmaker, B. Huntsman, of York, and metal produced by his method is very highly prized at the present day. Many other methods have been since introduced, amongst which may be mention the Bessemer and the Siemens-Martin processes, and steel is now produced from iron of very varying quality, so that the mark _cast steel_ is now far from being a guarantee of quality. The fusion of shear or cement steel will only secure a marked superiority in its quality under two principal conditions: (1) The metal must be carefully selected, since certain qualities do not intermingle thoroughly. (2) Very great care and skill must be devoted to all the operations, the successive heatings, forging, rolling, etc.

In short, in the case of steel it is exceptionally true that we must never accept the metal merely on its own recommendation. Whatever maker’s mark is selected, the results obtained will never be satisfactory unless the degree of hardness, the elasticity, cohesive force, etc., are such as will suit the metal to the special purpose to which it is to be applied as well as to the working it will

have to undergo. _Experiment can alone make us fully cognizant of the qualities of a steel._

GENERAL OBSERVATIONS.

=63.= All steels, if of good quality to begin with, will deteriorate if subjected too often or too long (according to the character of the metal) to the action of either the fire or the hammer. They will become brittle and incapable of hardening, in the end even reverting to the condition of iron.

The quality of steel becomes worse as the number of flaws, blackish filaments, more or less carbonaceous veins, and occasional particles of pure iron in its substance are greater; as its surface is _cindery_, that is to say spotted with minute black marks which become more prominent after polishing, etc.; as its fracture presents an uneven grain, etc.

Such a metal is found to vary considerably as regards hardness, elasticity, etc.; not being uniformly affected in the hardening, it becomes difficult to work with the file and almost impossible to form into a perfect cylinder in the lathe.

Other conditions being equal, these faults are characteristic of natural steel rather than of the two other varieties. At the same time, if well sheared, it becomes very elastic, and has the great advantages of not being deteriorated under the hammer and of being less ready than the other varieties to be converted into iron.

Rolling, wire-drawing and hammering occasion a molecular re-arrangement; it is necessary, therefore, to anneal the metal from time to time, as otherwise it becomes brittle or cracks.

There is a certain temperature, corresponding to each variety of steel, which cannot be exceeded without the metal being injuriously affected; this temperature must, then, be previously determined.

The grain of a piece of steel that has been superheated or _burnt_ is characterized by brilliant diamond-like particles; the mass loses its beautiful color, and resembles iron more or less according to the degree of heat applied.

Some few workmen are enabled, by long experience and a very delicate touch, to judge approximately of the quality of a steel from its weight, feel, and resonance. Metal that is of a good quality, homogeneous, and very dense, they term _full_.

SPECIAL OBSERVATIONS.

=64.= =Natural Steel.= In the case of natural steels of low quality, the fracture is usually characterized by uneven grains, a somewhat fibrous nature and a bluish tint. The grain becomes finer and more even and the surface presents more and more the appearance of a piece of coke, as the quality of metal improves. In addition to these distinctive features a natural steel of high quality can be distinguished by the fact of its being more thoroughly hardened and less liable to break when hard.

In hardening it must be raised to a higher temperature than cement steel; in other words, steel of a low quality must be heated somewhat above bright redness, while the better qualities should be heated to an orange-red, or nearly so (=77=).

=65.= =Cement Steel.= The cement steel ordinarily met with has a lamellar fracture, the lamellæ varying in form and color from the center towards the circumference. The grain is usually finer and more uniform than that of natural steel, there is seldom any appearance of fibres, veins, or flaws. The color of the fracture is greyish, tending towards blue in the ordinary qualities.

The better qualities are marked by a closer grain, a more uniform, dull, greyish-white color, exhibiting neither streaks or black spots after hardening, and by the further fact that hardening can be effected at a lower temperature. If of the very best quality, it should not require heating beyond a clear cherry-red; often even a still less degree of heat will suffice.

=66.= =Cast Steel.= Cast steel is the most homogeneous, full, and beautiful of the three classes. Several varieties exist. The fracture of cast steel, as compared with others, is smooth, compact, and of a white-grey color, resembling coke. The grain is fine and very even. The metal must be hardened at a temperature much lower than can be safely applied to other classes of steel, since it is rapidly deteriorated by heat.

Cast steel is more fusible than ordinary steel, and will fracture with ease under the hammer when heated to a blue tint, so that great care is essential in hammering it.

The metal should never be heated beyond a dull or cherry-red heat, lest it be _burnt_.

The tenacity will be increased by forging at a low temperature or even by cold hammering.

The fineness in grain, together with its high density, afford an indication that the metal can be rendered very uniformly hard; that very fine cutting edges and the most minute rods can be made of it; and that, after hardening, it can be highly and uniformly polished; in other words, that it does not exhibit spots or streaks differing in color from the mass, as is always the case with natural and cement steels. For most horological purposes (such as making pinions, staffs, pivots, etc.) cast steel is preferable. It is the only kind that can with certainty be highly polished, turned perfectly round, and that does not get distorted in the smoothing. Moreover, when wear does occur it exhibits less irregularity.

Highly-carbonized shear steel exhibits a fine, close grain that would make it easily mistaken for cast steel. They can be best distinguished by the application of dilute sulphuric acid. The side of the bar when acted on by this means exhibits lines that indicate the junctions of the several layers constituting shear steel.

DETERMINATION OF THE QUALITIES OF STEEL.

=67.= It is unnecessary to observe that as we are writing mainly for the use of practical watch and clockmakers, we shall make no reference to those elaborate systems of testing that form a remarkable feature of the engineering of the present day, but shall confine ourselves to the tests which workmen can apply for themselves.

When the grain is fine, close and homogeneous, the fracture in even curved lines and the surface of a uniform grey aspect, the metal is considered to be of good quality. It is, nevertheless, unsafe to rely too much on such indications, for a steel that has been hammered until cold will exhibit a fine close grain, whereas the grain of the same metal will be coarse and open if it was still red hot when the hammering or rolling was concluded. The grain of hardened steel, moreover, depends on the degree of heat to which it has been subjected.

When of equal quality, even if from the same maker, the grain will be finer in bars of small dimensions than in those that are larger.

Cast steel even, especially in large pieces, is not always perfectly homogeneous, as can be easily perceived on applying the file, or still better, in the lathe; an object can with difficulty be turned perfectly round, and loses its shape in the smoothing. _As a general rule it is impossible to form a reliable opinion on a specimen of steel until after it has been worked, filed, turned, and tested according to the particular use to which it is to be applied; for a steel that is excellent for making, say, a spring or a cutter, may be quite unsuitable and give most unsatisfactory results if used for making staffs or fine pivots, or the converse may be equally true._

As a preliminary test, break a piece of the metal; after having examined the fracture, form a cutting edge, harden to what seems to be a convenient degree, then sharpen and employ for cutting small pieces of iron. If the edge is in no way damaged by the iron, this may be taken as a good indication that the metal possesses body and tenacity, and that it can be hardened as much as is required for such purposes.

The following are methods of obtaining more complete information as to the homogeneity, the character of grain, the degree of hardness a given sample can attain, as well as its malleability, body, elasticity, etc.

=68.= =Homogeneity.= Place drops of dilute sulphuric acid equidistant along the surface of a bar. If the metal is homogeneous all the drops will impart the same color.

Cold hammer or hammer-harden, and then fire-harden part of the bar. Break off the extremity in order to study the fracture; if the result of this examination is satisfactory, polish the hardened end carefully, and with the aid of a glass again examine into the homogeneity of the metal. The polish will be the better and more uniform according as the steel is more homogeneous.

=69.= =Grain, hardness and temperature of hardening.= All varieties of steel do not harden to the same degree, and each requires to be heated to its own particular temperature for hardening; moreover, the character of the metal, its color, and the size of its grains vary according to the degree of heat to which it is subjected. It would be difficult to draw any exact conclusions as to the character of grain and the hardness without the following practical method, which we owe to Reaumur:

At a temperature not exceeding a dull redness, forge a piece of the steel to be tested into the form of a razor-blade, that is to say, leaving it thick on one edge and thin on the other, in the direction of its length. Then heat the blade, holding it by one end, and when the other end has reached a bright red heat, plunge the whole into water. Part of the steel will then be hard hardened. Along the

entire length of the thinner edge carefully break off the metal with a hammer or otherwise, and examine the character of grain at different points of the exposed thicker edge thus left.

As the form, color, etc., of the grain depend on the degree of heat to which each portion was subjected, it follows that we shall observe four types of grains: (1) Large, white, sparkling grains; (2) Grains that are medium sized and intermixed, some being white and sparkling, others white and dull; (3) Fine dull grains; and (4) Grains that are medium sized, but dull and ill-defined.

According as the third class of grains is observed to be more numerous than the second class, so is the fineness of the steel greater, and conversely.

This method of testing possesses, moreover, the advantage that the workman can experiment on his blade of steel with a view to determine the temperature best suited for hardening.

Grain No. 1 corresponds to a white-red heat for hardening.

Grain No. 2 corresponds to an orange-red heat for hardening.

Grain No. 3 corresponds to some shade of cherry-red heat for hardening.

Grain No. 4 corresponds to a dull red heat for hardening.

As there is some difficulty in remembering the exact points at which these several temperatures are reached we will complete this account of the mode of testing by the following:

=70.= On a thick plate of metal, maintained at an orange-red heat, place three fragments of the steel under examination, previously marking them, so as to observe the order in which they are immersed in water; and have three vessels of water standing near. As soon as one of the pieces reaches a dull cherry-red heat, allow it to slide into one of the vessels; heat the second to a medium cherry, and the third to a bright cherry-red, introducing them in succession into the water-vessels. If these pieces be examined as to the resistance they offer to breaking, and the fracture of each be compared with the fracture at different points of the razor-blade, the file being used to test hardness, we shall have sufficient evidence as to the most suitable temperature for the hardening of this particular variety of steel.

=71.= =Body.= A steel that possesses _body_ is not brittle. This quality may be tested in the following manner: Several bars of different kinds of steel, of equal dimensions and hardened as uniformly as possible, are bent until the breaking point is reached. If all the conditions of the trial are identical, those bars that stand the greatest angular deflection without breaking have the most body.

Steel that possesses body does not break as easily as that which is wanting in body. Its fracture will be, as it were, bevelled off like the mouth-piece of a whistle. If soft and fibrous, it will be characterized by parts being torn asunder.

=72.= =Elasticity.= The elasticity may be tested in a similar manner. It is proportional to the curvature or to the weight that a rod or blade of the metal under examination can support without failing to return to its initial position as soon as the weight or obstacle is removed. A sample of steel that is distorted by a weight that another specimen resists, is evidently inferior in elasticity.

=73.= =Malleability, tenacity, ductility.= A cold hammering, if carefully managed, will suffice to indicate the limits between which steel will support frequently repeated percussion, without breaking, cracking or flying.

Forge a piece, introducing it a number of times into the fire in order to ascertain whether it loses its distinctive characteristics rapidly, and whether it can be successfully forged.

It is more difficult to forge, according as it is harder and more “steely.”

The degree of malleability is indicated by the manner in which it supports hammering and rolling, and by the smallness of the dimensions to which it can be brought by such operations.

Passing the metal through a draw-plate with smooth holes, or tapping it in a screw-plate will give useful indications as to degree of ductility and tenacity.

A metal is said to be _malleable_ when it can be easily spread out under the hammer or in the laminating rolls. It is called _ductile_ when it can be reduced to very thin wire by passing through the draw-plate.

It would seem that these two properties, ductility and malleability, should always exist together, to the same degree, in any given metal, but such is not the case. Iron can be drawn into very fine wire, but cannot be reduced to sheets of relatively equal thinness; tin and lead give leaves of extreme thinness, but cannot be drawn out into very fine wires; gold and silver are both very malleable and ductile, and they rank highest as regards the possession of these properties.

Steel is more fusible and malleable than iron, but less ductile.

=74.= _Observations._ Formerly the makers of cylinder escapements preferred forged steel, and their cylinders often cracked after the hardening: modern makers employ drawn steel, and it is much preferable. At the same time they do not appear to recognize the principal reason for the difference in the two varieties of steel. It seems to us to be as follows: forged steel is malleable; drawn steel, which has passed well through the draw-plate, is ductile, and, therefore, tenacious. But tenacity in a metal is nothing else than an exceptional resistance, opposed by its particles to a fracture or separation; it follows, then that drawn steel will crack with less facility than the other.

PREPARATIONS OF STEEL.

=75.= When a variety of steel has been selected that possesses the requisite properties: that is to say, fibre and elasticity for springs; body and tenacity for circular cutters, gravers, etc., it must be prepared; in other words, it must be made so that it can be worked with ease, for steel that is badly prepared will resist both the file, the graver and the drill. It can never be turned perfectly round, and will harden unevenly.

=76.= =To anneal steel.= The commonest, and at the same time best, method consists in heating the metal to a dull, red heat, burying it in hot ashes and allowing it to cool slowly.

Steel raised to a red heat in contact with air loses a portion of its carbon, so that it is better to place the metal in a vessel of burnt clay; this is introduced into a fire which must not be too bright at first, and when the vessel has attained a red heat the fire is checked and left until the whole is quite cold.

In order to soften steel by annealing with a view to work it, engineers entirely cover the metal with dry powdered wood charcoal or dry iron filings or turnings, in a cast iron box or pot, or in a crucible, shutting up all the openings so as to protect it from the direct action of the fire and from the air. The vessel is then put in a dull fire, the heat being gradually raised until the whole has acquired the requisite temperature, which is known by observing the color (see the following table); this degree of heat is maintained for about ten minutes and the fire quenched, after which it must be allowed to gradually die out. Frequently the cooling is not complete for a day or two, and even more when the crucible is of large dimensions.

The metal will become softer, according as the cooling is more slowly effected. It is generally heated to 800° or 900° C. (1500° or 1600° F.), a cherry-red heat. When the steel is associated with brass, as in the case of a compensation balance, it is not safe to exceed 600° C. (1000° F.)

=77.= It will be useful here to give the following table, compiled by Pouillet, of the temperature, as indicated by the air-thermometer, corresponding to various colors of a heated body:

Incipient red heat corresponds to 525° C. (980° F.) Dull red ” ” ” 700° C. (1280° F.) Incipient cherry-red ” ” 800° C. (1470° F.) Cherry-red ” ” 900° C. (1650° F.) Clear cherry-red ” ” 1000° C. (1830° F.) Deep orange ” ” 1100° C. (2010° F.) Clear orange ” ” 1200° C. (2190° F.) White ” ” 1300° C. (2370° F.) Bright white ” ” 1400° C. (2550° F.) Dazzling white ” 1500-1600° C. (2730-2910° F.)

=78.= _Annealing or softening in water._ Instead of allowing a piece of steel to cool slowly, it may be thrown into water when heated to a temperature just below that at which it would harden. In this case the metal will not harden, but, on the contrary, become very soft. A single operation suffices for certain varieties of steel, but with others it must be repeated.

The only difficulty consists in fixing upon the precise moment at which the metal has the requisite tint (a purplish yellow or dull red), and this is more especially felt when dealing with small pieces; experience can alone guide the workman in this matter.

A skilful workman recommends the employment of water containing one-fifth of its weight of gum arabic. He also recommends that the metal be wiped over with an oiled rag, then held in the fire, and, as soon as the oil is converted into a thick smoke, and is on the point of igniting, to immerse in water.

=79.= =Hammering steel.= Watchmakers who are called upon to manipulate exceedingly small pieces of steel, can somewhat increase the body and homogeneity of the metal by a cold hammering. After annealing, the object is hammered with light, uniform blows, again annealed, and the same operation is repeated one or more times, according to the degree of malleability already acquired by the metal. Steel thus prepared has more body; the particles composing it are more closely pressed together; it files and turns well, can be heated more evenly, and is not distorted or only very slightly in hardening, providing the requisite precautions are taken.

=80.= _The hammer and anvil._ It is important that in these operations the surfaces of the hammer and anvil employed be perfectly smooth and even polished. If they are rough or cracked, if they are uneven or have a grained surface, a flaw will be produced in the body of the steel or a crack on its surface.

=81.= =To clean rough steel.= The black coating known as “scale,” which covers the surface of the metal after it has been in the fire, will rapidly spoil gravers and files, and, in addition to this, it leaves behind in them excessively hard particles that will become imbedded in the steel itself after a clean surface has been exposed. It is then essential, in order to ensure good and rapid workmanship, to previously remove this crust from the surface.

This can be done in two ways: by using a rapidly-revolving grindstone, which instantaneously removes the oxide, at the same time smoothing the surface of the steel; or by leaving it for a sufficient length of time in dilute acid, by which the superficial oxide is dissolved.

Sulphuric acid is usually preferred; in addition to the cleaning, it is said to produce an effect somewhat similar to annealing. On withdrawal from the acid, the steel must be thoroughly washed with water and wiped dry with care.

=82.= =Ordinary mode of preparing steel.= When the metal has been annealed by one of the methods indicated above, its preparation is completed by “pickling” in acid, after which it is hammered cold between an anvil and hammer (=79=, =80=). When the metal has been worked, it is heated to a bluish tint, and after cooling slowly is ready for the hardening.

=83.= _M. Covillot’s mode._ This author adopts a method whereby he obtains steel that is very soft to work and perfectly free from hard grains or “pins” of cast iron, which are so often to be met with in steel, causing it to crack in consequence of their inability to spread under the hammer.

Take some garlic, the younger the better, mix it with sufficient good walnut-oil to cover the garlic and form into a paste; then place it in an earthenware pot on the fire. When beginning to boil, heat the steel to dull redness and plunge it into the boiling paste. Withdraw it with a quantity of oil and garlic adhering; again heat to redness and plunge into the paste. This operation may be repeated two or three times. Then heat the steel, while inclosed in an iron tube or box placed on the fire, and allow the whole to cool. Finally, the steel may be finished by setting it to _cook_ (if we may use such an expression) for ten or twelve hours in the composition of garlic and nut-oil.

The last operation may be performed by setting the boiling solution over an oil-lamp, after depressing the wick in such a manner that the paste may be kept just simmering.

M. Covillot employed the same mixture for hardening the objects; but then, of course, it must be cold.

HARDENING.

=84.= It is well known that by the operation of hardening, which consists in heating a piece of steel to a red heat and immediately chilling it, the hardness is very materially increased.

Hardening increases the dimensions of the object. A steel collar adjusted to fit a cylinder will slide on more easily after hardening.

Rolled steel is more liable to be distorted in the hardening than metal which has been forged or hammer-hardened. As a general rule, when steel—especially cast steel—has been carefully annealed, cold-hammered and, after working, heated to a blue temper

and slowly cooled, it will not be distorted in the hardening, providing the heating is skillfully conducted, and if, at the moment of introducing the object vertically into the bath, the heat is evenly distributed throughout. Some practical men affirm that the mere presence of an oily layer on the surface of the water will check the tendency to distortion.

A workman frequently pretends that he has some exceptionally good solution for hardening, of which a great mystery is often made; but it is very generally admitted by those who are well-informed that these so-called secrets are a delusion and in no sense superior to pure water. There is a certain amount of truth on both sides, and the former class are somewhat justified by experiments with the various solutions enumerated below. We may, however, lay down the three following conditions as essential to the successful conduct of the operation of hardening: (1) _The steel must previously be carefully prepared and worked_; metal that has been skillfully hammered cold or below a red heat, for instance, will harden better than when not so treated; but if hammered too much or carelessly, it will crack; (2) _The method of heating_ should be such that the heat is evenly distributed throughout the object; if, on immersion, its temperature is not uniform, the degree of hardness will vary; (3) _The skill of the workman_ must enable him to detect the exact degree of heat the variety of steel can withstand, and this must on no account be exceeded, for in that case the steel will lose tenacity, will be more or less _burnt_, &c. In the case of irregular shaped articles, considerable skill is often needed to ensure that the several parts of the mass shall be cooled at, approximately, the same rate.

=85.= =Methods of hardening.= The baths used for hardening may be classed under three heads: _Tough_, _Hard_, and _Glass-hard_. It must be understood, however, that these classes may be made to merge more or less into one another, by varying the degree of temper.

=85a.= The following receipts are drawn from various sources, and the reader is recommended to select the one which he finds on trial to be best adapted to his requirements, for, as Prof. Akerman has pointed out, there are very many conditions exceedingly difficult of calculation that influence hardening, and hence it follows that a workman accustomed to hardening often considers that only one method, which he has been in the habit of employing, can be used for a certain purpose, while another equally skillful workman can only attain the same result by a method essentially different.

I. _Tough._ Tallow; tepid water; oil; resin; sealing-wax; lead; beeswax; a solution of 3 to 4 parts (by weight) of gum arabic in 100 parts of water; 1 part of soft soap in 100 parts of water; cold water with a layer of oil over it, the thickness of which varies with the degree of hardness required; 10 parts mutton suet, 5 parts resin, 2 parts sal-ammoniac, and 35 parts olive oil.

II. _Hard._ Cold water; water containing various salts, such as sal-ammoniac and sea-salt; a solution of 5 parts sea-salt and 1 part sal-ammoniac in 20 parts of water; 4 parts sulphuric acid, 50 parts sea-salt, 10 parts alcohol, and 1,000 parts water (all by weight); 4 parts sulphuric acid, 1 part nitric acid, 1 part pyroligneous acid in 1,000 parts water (to be used very cold).

III. _Glass-hard._—Mercury; nitric acid; opium; any cyanide.

=86.= As a rule it is well to employ tallow for the hardening of small objects in which hardness without brittleness is needed. Oil renders the surface harder than the interior, and soapy water has the same effect. Saline solutions generally give great hardness. Very minute drills may be hardened by simply whisking them about in the air after heating the blade to redness, and small objects may be hardened by pressing between two cold surfaces, as those of the hammer and anvil.

If hardened in nitric acid, opium, or mercury, the hardness of steel is so great that it will easily cut glass. But such steel is brittle and all the more delicate according as the precise temperature necessary (which is not very high) has been exceeded. For it must always be borne in mind that steel which has been heated too highly has deteriorated in quality and will remain brittle.

=87.= =Precautions to be observed in hardening.= In the case of delicate pieces it is necessary to avoid the use of the blow-pipe, as the current of air causes the surface to scale, and, as is well known, the metal being unevenly heated will be distorted in the hardening, and will not be uniformly hardened.

It is better to enclose the article between two pieces of ignited charcoal, or in a metal tube, or to bring it in contact with a sufficiently hot piece of metal, etc. An excellent plan is to heat the article in a bath of hot lead, or of lead and tin in proportions dependent on the temperature required. The heating is thus exceedingly uniform, and, if operating in a dark room, the temperature can be accurately judged.

When it is required to harden an object without discoloring the surface or destroying the polish, it may be placed in a tube, and completely surrounded with powdered wood charcoal, or, preferably, animal charcoal. The whole after being heated is plunged in water without the steel being in any way exposed to the air. The powder must be heaped up as a precaution against access of air. On being taken from the water, the steel is at once placed in alcohol, and if at all dull it will generally be only necessary to rub the surface with a little rouge.

It is essential that the animal charcoal be previously heated in order to expel moisture, as otherwise it would adhere to the surface and produce marks and even irregularity in the hardness.

As a rule the object must be immersed in the cooling liquid vertically in the direction of its greatest length, and if of unequal thickness, the stout portion should touch the surface first, so that the metal may cool more uniformly. In hardening large masses of steel, various devices are resorted to in order to insure uniformity in the cooling, but space prevents us from entering more fully into this interesting question.

The vessel must be of such a depth that the object will not reach the bottom until quite cold. It is liable to distortion if introduced sideways, or if the vessel is too shallow.

The method described above for protecting the surface from the action of the fire should be adopted when hardening delicate or complicated articles; but in the case of drills, for instance, a simple coating of one of the following preparations is sufficient.

When an object is hardened in a saline solution, it is well to cover it with a paste composed of water, salt and flour (some use yeast and salt for this purpose), or a thin clay. This precaution prevents any blistering or oxidation of the surface. If it be desired to avoid oxidation, and, at the same time, to restore to the steel the carbon it has lost owing to the action of the fire, it must be rolled, while still wet, in another paste, containing powdered horn or leather, or some such calcined animal matter. Delicate parts can also be protected by a layer of beeswax and olive oil made hot.

In hardening small drills, very good results are obtained by enclosing the blade in a pellet formed of prussiate of potash, lard and Castile soap, and cooling in beeswax, or the surface may be protected by a layer of soft soap.

Steel as forged, that is with the thin scale on, is less liable to break in hardening than if previously brightened, for the scale causes it to cook, and, therefore, contract more slowly. At the same time it should be borne in mind that when the surface is bright the hardness will be somewhat greater.

It will be well to warn the beginner that, if an object is not entirely immersed in the cooling liquid, it should never be held still, but rapidly moved up and down, as otherwise there is a liability to crack at that part which was level with the surface.

As a watchmaker only uses steels of the best quality, he should, in hardening never exceed a cherry-red heat, and cherry-red comprises three distinct tints (=77=); incipient cherry-red, cherry-red, and clear cherry-red. The second of these should not be exceeded in hardening cast steel, and the third should be taken as an extreme limit in the case of shear steel.

Ice-cold water should never be employed, but the extreme chill should be first taken off. Indeed, it is found that frosty weather interferes materially with the operation of hardening.

Some workmen maintain that the hardening is done better if the water has been long used for the purpose without renewal.

TEMPERING.

=88.= Hardened steel is extremely fragile, but its tenacity may be restored by _tempering_, that is to say, by heating it to a degree dependent on the amount by which its original softness has to be restored. The color of the metallic surface will gradually change as the temperature rises, each tint corresponding approximately to the degree of heat given in the following table (Stodart):

1. Very pale straw yellow 220° C. (430° F.) } 2. A shade darker yellow 235° C. (450° F.) } Tools for metal. 3. Darker straw yellow 245° C. (470° F.) } Tools for wood and 4. Still darker straw yellow 255° C. (490° F.) } screws, taps, etc. 5. Brown yellow 260° C. (500° C. 500° F.) } Hatchets, chipping 6. Yellow, tinged slightly } chisels and other with purple 270° C. (520° F.) } percussive tools, 7. Light purple 275° C. (530° F.) } saws, etc. 8. Dark purple 290° C. (550° F.) } 9. Dark blue 300° C. (570° F.) } Springs. 10. Paler blue 310° C. (590° F.) } 11. Still paler blue 320° C. (610° F.) } Too soft for the 12. Still paler blue, with tinge } above purposes. of green 335° C. (630° F.) }

=89.= It will facilitate the precise determination of these points if it be remembered that

An alloy of 1 part lead and 1 part tin (by weight) melts at 196° C. (385° F.) Metallic tin ” ” ” 230° C. (446° F.) An alloy of 2 parts lead and 1 part tin ” 240° C. (465° F.) Metallic bismuth ” ” ” 270° C. (520° F.) An alloy of 5 parts lead and 1 part tin ” 290° c. (550° F.) Metallic cadmium ” ” ” 310° C. (590° F.) Metallic lead ” ” ” 320° C. (608° F.)

=90.= Before proceeding to temper an object, at least one of its faces must be smoothed with pumice-stone, oilstone dust, or emery paper, and the surface must be left perfectly clean, care being taken to avoid contact with the fingers, as otherwise it will be difficult to ensure the requisite tint being obtained.

Tempered to any shade between Nos. 1 and 6 the steel will, if previously well hardened, be left too hard to be worked by a file or graver; heated beyond No. 10, it can no longer be much bent without distortion.

When the quality and the degree of hardness of steel differ, the temper corresponding to a given tint will also vary. As a rule, hardened cast steel, tempered to No. 8, will be found as soft as natural steel which has been let down to No. 9, or even to No. 10.

A piece of steel can be let down to the same tint several times in succession without altering its properties.

If a good and uniform color is desired, the steel must be highly polished, as the oxidation of rough parts will render the tint irregular. The rouge employed must not be too dry, and, if the burnisher is used, care should be taken that it acts on the entire surface. Metal of a bad quality, which will not take an even polish, can rarely be nicely blued.

When the object is finely _smoothed_ with a uniform white surface, very good results may be obtained; but in such cases the cleaning must be carefully conducted, as the presence of minute greasy particles will always render the color irregular, and may even entirely prevent its appearance.

A uniform color can only be obtained by heating the object in such a manner that its temperature is raised evenly throughout.

The tempering may be performed by placing an object on the _bluing tray_, a thin metallic plate, often covered with a thick layer of fine brass filings, which should be renewed for each operation; or on a thick piece of metal previously heated to a sufficient degree; on ignited charcoal covered with a layer of white ash; in a bath of molten metal, the temperature of which corresponds to the requisite degree of heat, or the object may be laid on the surface of such a bath, etc. Some watchmakers when letting down a piece of steel immerse it in water to check the action; but by so doing they produce an exactly contrary effect. If a piece of steel be cooled suddenly in water as soon as it assumes any given color it will be _softer_ than if left to cool in the open air (=78=).

At one of the blue tints, steel possesses its _maximum elasticity_. The exact shade varies with the different qualities of steel.

If a hardened and tempered spring has lost its initial elasticity, this may be restored or even improved upon by gently hammer-hardening, and after whitening with emery, again tempering to the proper blue tint.

=91.= A very convenient way of tempering a large number of small articles at a time, heating them with absolute uniformity, is to place them in a small vessel with sufficient tallow or cold oil to cover them; the whole is then heated to the requisite degree, which may be determined by a thermometer or by observing the smoke. When smoke is first seen to rise, the temper corresponds to No. 2 in the table (article =88=). Smoke more abundant and darker corresponds to No. 5. Black smoke still thicker, No. 7. Oil or tallow takes fire with lighted paper presented to it, No. 9. After this the oil takes fire of itself and continues to burn. If the whole of the oil is allowed to burn away, the lowest temper in the table is reached.

It is often convenient to simply smear an article with oil or tallow, and hold it over a flame or piece of hot iron. The temper can then be judged in the manner just explained.

With a view to combine the two operations of hardening and tempering, M. Caron suggested that the temperature of the water used for hardening be heated to a pre-determined degree. Thus the requisite temper may be given to gun-lock springs by heating the water in which they are hardened to 55° C. (130° F.).

TO WHITEN AND BLUE STEEL.

=92.= Some makers of watch-hands and balance-springs, when they are not satisfied with the color assumed by an object in tempering, immerse it in an acid bath, which whitens it, after which the bluing operation is repeated.

We have seen watchmakers whiten small pieces of steel with a piece of pith moistened with dilute sulphuric acid, but the method cannot be recommended.

Others fix fine steel work, a watch-hand for example, with wax on a plate, and whiten it by means of pith and polishing rouge, or a small stiff brush charged with the same material. It is then detached, by heating, and cleaned in hot alcohol.

These methods, if judiciously employed, are of great service, but it is important to remember always to thoroughly wash after the use of acid, and then to allow the object to remain for a few minutes in alcohol.

Sulphuric acid does not whiten well. It often leaves dark shades on the surface. Hydrochloric acid gives better results.

=93.= =To blue steel uniformly.= In order to secure a uniform color in tempering or bluing, it is essential that the smoothing and polishing should have been very evenly done. The surface must be perfectly clean; for otherwise parts that are greasy, or on which the rouge has remained too long, or has been too dry, will not exhibit the same tint as the rest. The heat must be uniformly distributed. This is why, when bluing screws in a perforated bluing pan, it is customary to lightly strike the handle, for the vibration and the perpetual change in the contacts ensures their receiving the heat more evenly. A similar purpose is served by placing the pieces in brass filings. Steel must not be tempered while only in contact with bodies that are bad conductors of heat, stone, either in powder or block, for example; because, as we have already observed, the distribution of heat would occur unevenly throughout the metal.

Watchmakers secure a uniform tint more easily by using an iron or copper polisher than one of any other metal.

=94.= _To blue small pieces of steel evenly._ If the foregoing precautions are carefully observed, the following methods will give satisfactory results:

First blue the object without any special regard to uniformity of color. If it proves to be imperfect, take a piece of dead wood that does not crumble too easily, or of clean pith, and whiten the surface with rouge without letting it be too dry. Small pieces thus prepared, if cleaned and blued with care, will assume a very uniform tint.

A clever mechanic assures us that he easily obtains a similar result by rubbing the surface, after it has been well smoothed, with the end of a stick that has been partly burnt in the fire.

=95.= _To blue a clock hand or a spring._ To blue a piece of steel that is of some length, a clock hand for example; clockmakers place it either on ignited charcoal, with a hole in the center for the socket, and whitened over its surface, as this indicates a degree of heat that is approximately uniform, or on a curved bluing tray perforated with holes large enough to admit the socket. The center will become violet or blue sooner than the rest, and as soon as it assumes the requisite tint, the hand must be removed, holding it with tweezers by the socket, or by the aid of a larged-sized arbor passed through it; the lower side of the hand is then placed on the edge of the charcoal or bluing tray, and removed by gradually sliding it off towards the point, more or less slowly according to the progress made with the coloring; with a little practice, the workman will soon be enabled to secure a uniform blue throughout the length, and even, if necessary, to retouch parts that have not assumed a sufficiently deep tint.

Instead of a bluing tray, a small mass of iron, with a slightly rounded surface and heated to a suitable temperature, can be employed; but the color must not form too rapidly, and this is liable to occur if the temperature of the mass is excessive. Nor should this temperature be unevenly distributed.

A spring after being whitened can be blued in the same way. Having fixed one end, it is stretched by a weight attached to the other end, and the hot iron is then passed along it at such a speed that a uniform color is secured. Of course the hot iron might be fixed and the spring passed over it. A lamp may be used, but its employment involves more attention and dexterity.

=96.= =Bluing as an indication of temper.= This subject has already been very fully considered in article =88= to =90=. When the color assumed by a piece of steel does not require to be preserved, and it is only necessary to temper the object at a certain temperature, the means best adapted to expedite the operation will naturally be sought. Thus, in factories, large numbers are tempered at once in a bath of tallow, oil, etc. The workman, in judging temper by color (=88=), must have enough experience to

enable him to determine, for a given sample of steel, what are the successive colors as well as the temperature of the bath, etc. His success is certain; but it depends on the experience, and, therefore, on the sense of sight of the operator, and, we should again add, on the knowledge he possesses of the qualities of the steel he is using.

CASE-HARDENING.

=97.= This process is often resorted to when a hard surface is required on objects of wrought iron, for example the face of an anvil. It is the exact converse of the method already described in article =59= for obtaining malleable castings, and consists in heating the object to a red heat in contact with charcoal, or some substance containing carbon; this enters into the surface iron, converting it into steel. Or after heating to a bright redness the object may be sprinkled over with prussiate of potash, returned to the fire, and after a few minutes cooled by immersion in water. When a greater thickness of steel is needed, or when dealing with large articles, they must be enclosed in wrought-iron boxes, and bedded in such substances as fragments of horn, bones, leather cuttings, etc; the box is then luted up and the whole maintained at a red heat for twelve hours, after which the fire is allowed to die out. Articles may sometimes be case-hardened by coating with a paste of arsenious acid, powdered leather, horn, or other nitrogenous body and hydrochloric acid, and then heating them to bright redness in a muffle or other suitable furnace.

INFLUENCE OF FOREIGN METALS AND METALLOIDS ON THE QUALITIES OF IRON AND STEEL.

=98.= It would be impossible to give a full account of this subject in the space at our disposal, and the reader must be referred to works on the metallurgy of iron and steel for details in regard to the remarkable influence of minute traces of phosphorus, tungsten, silicon, manganese, arsenic, etc., on the mechanical and chemical properties of those metals.

COPPER.

=99.= Copper is an elementary body of a reddish-brown color, which must not be confounded with brass, occasionally termed yellow copper. In tenacity it comes next below iron, breaking with a strain of 34 kilo. per sq. mm. of section (or 48,000 lbs. per sq. inch).

In horology, the only use made of the pure metal is for the construction of compensation pendulums on the gridiron principle, and as wire in electric clocks. It is also employed, when rolled into thin sheets, for a base to receive the enamel of watch dials, in consequence of its expansion being about the same as that of the enamel, which does not therefore crack in the cooling.

The copper of commerce is seldom pure, and this gives rise to many of the imperfections met with in ordinary brass.

ZINC.

=100.= This is an elementary metallic body of a bluish white color. It is used in the form of rods, for compensation pendulums.

It must be obtained of great purity, whether it is employed by itself or to alloy with another metal. The presence of foreign bodies in zinc, even in very small quantities, has a marked influence on the physical properties of an alloy into which it enters.

The purer the metal the more easily will it roll, and this fact can be taken advantage of as a test of quality.

Although very brittle at 0° C. (32° F.) and 200°C. (400° F.), it has a maximum malleability at about 100° C. (212° F.), the boiling point of water; it should, then, be heated to this degree before bending, rolling, hammering, etc.

It may be annealed in boiling water, or by heating to such a temperature that water hisses when allowed to drop on to it.

It melts at 420° C. (790° F.) and volatilizes if raised to a red heat.

A sudden cooling, or the presence of arsenic or antimony, will render zinc brittle. It must not be melted in cast iron vessels, as the quality of zinc is deteriorated by the small quantity of iron it takes up under such circumstances.

This metal possesses a great affinity for oxygen, and therefore oxidizes very readily when fused.

It is usual, before pouring zinc that is intended for rolling, to throw some pieces of the solid metal into the molten mass, the object being to somewhat reduce the temperature, and thus prevent a too rapid cooling, as, in that case, zinc is very brittle.

BRASS.

=101.= Pure copper is difficult to work with the graver or file, but such is not the case when this metal is alloyed with zinc; we then obtain brass, or, as it is sometimes termed, yellow copper.

Alloys containing copper, zinc, and tin are termed bronzes.

If a small quantity of lead, about 1 per cent. of its weight, be added to brass, it renders the metal less fibrous, imparting to it a certain degree of brittleness so that it is more easily worked with the graver, file, drill, or the saw.

When the brass is required to be hammered, a portion of the lead is replaced by tin; by this means the metal becomes more malleable, or, in terms of the workshop, soft.

The color, tenacity, ductility, malleability, etc., vary with the percentage composition of the alloy. It is, then, of the utmost importance that a watchmaker be able to test and select the brass before employing it in his work; metal that is excellent for wire-drawing, for example, would be utterly useless for making an escape wheel, since it would become distorted in the cutting in consequence of its ductility. It belongs, in fact, to the class of metals that will extend under the hammer without hardening (very soft brasses).

The following is given as an analysis of brass very frequently employed in horology: copper, 66 per cent., zinc, 33 per cent.; and lead, 1 per cent. But it must not be forgotten that this is only to be taken as a mean. Both the proportions and the qualities vary with different makers, doubtless also according to the degree of purity of the metals employed in their manufacture.

=102.= =To select brass.= By following the directions given below any watchmaker should be able to select the brass best suited to his special requirements.

When the copper is in excess, zinc being proportionately reduced, the brass is usually soft and of a beautiful golden color. On the other hand, as the proportion of zinc is increased, the brass becomes more and more brittle, and at the same time, more fusible; the color changes to a light yellow, ultimately becoming greyish-white, and brass of this nature is said to be “hard.”

Very soft brass chokes the file, and spreads without hardening under the hammer; very hard brass, on the other hand, is fragile, liable to crack when hammered cold, and breaks in passing through the draw-plate.

Metal of a good yellow shade, intermediate between the golden and the pale yellow color, passes well through the draw-plate, spreads out slowly under the hammer, but without cracking, until of about half the initial thickness, and then resists the further action of the hammer, which rebounds from it; such brass is usually found to be of good quality for watchwork.

A sheet of brass is rarely homogeneous. If, after pouring, the metal has been allowed to cool slowly, the interior will be crystalline, and there will be an uneven fracture. This will cause the tenacity, etc., to vary throughout the mass. Similar differences are occasionally to be observed between the two faces of the same plate, due to the phenomenon of _liquation_; that is to say, to a tendency that characterizes certain metals when melted together to separate from one another when the cooling is not affected under proper conditions.

If the two surfaces of a plate be scraped clean at several points, and drops, as nearly equal as possible, of very pure watch oil, be placed on these clean surfaces, it may be taken as a rough indication that the metals are uniformly distributed if the successive shades of color of the oil as time goes on are the same at all the points experimented upon.

Some watchmakers heat the brass to a red heat (which must never be exceeded), and plunge it into nitric acid (equal parts acid and water). By this means the entire surface is cleaned, and the above examination is facilitated.

HAMMER HARDENING OF BRASS.

=103.= =Plates.= The selection of the metal will depend on the purpose for which it is intended, and the thickness must be such that, when hammered till of sufficient hardness, it will approximately equal one dimension of the required object; for it is advisable to remove as little of the surface metal as possible, a plate always hardening much more at the surface than in the interior.

There is considerable difficulty in indicating clearly in a book the exact mode of conducting the operation of hammer-hardening, and the assistance of a competent master is essential, at any rate for the first few trials. It must suffice to point out that the anvil, with a slightly convex surface, and the hammer, of sufficient weight, must be in very good condition and, if possible, polished on their

faces; the head of the latter should be rather convex, and the pene or chisel end somewhat broad and gently rounded off in all directions, for it will be needed as a means of bending the metal upwards; the curvature being such that there is not a danger of starting a crack, etc., by its means. We have already spoken of these two tools (=79=, =80=); it is only necessary to add that a thick straw pad should be placed under the anvil or block.

When one is compelled to use brass that is too thick, so that there is much work to be done with the hammer to reduce the thickness to what is required, it is a good plan to commence by elongating the metal in one direction, striking with the pene of the hammer a series of parallel blows in the direction of the required elongation; when the thickness is two or three times that ultimately needed, the surface is smoothed with the hammer-head and annealed; then it is brought to the right thickness by another hammering in the manner explained below, but it should be again pointed out that, when possible, metal of a suitable thickness ought to be taken in the first instance, since too much hammering has a detrimental effect.

Before hammer-hardening a plate, it must be dressed, an operation which consists in rounding off the edges very carefully in order to prevent their cracking, and in rounding the bottom and sides of internal angles which, without such a precaution would occasion a rupture. After this is completed, proceed to the hardening, using a rather heavy hammer, and giving sharp blows along lines parallel to the sides of the plate; commence from one of the corners in the case of a square plate; and with a round plate let the blows be in circles. In the latter case, work from the circumference towards the center, at the same time gradually increasing the force of the blows, since the metal opposes a greater resistance towards the center. If the work is done evenly and without hurrying, the surface will remain fairly flat, a fact which should be verified from time to time by the aid of a metal rule.

Round plates are sometimes hardened by commencing to hammer in the center and working towards the circumference along two radii in opposite directions; that is along a diameter. This first diameter is then crossed by another at right angles; the intervals are filled in with other diameters that must not touch until the entire surface is covered, always taking care to work from the center towards the circumference.

When the metal is thin only the hammer-head is used, but beyond a certain thickness the pene of the hammer must be employed until about half the required thickness is reached; the surface is planished and the hardening finished with the face.

Blows that are irregular, too hard or roughly given, will cause the metal to crack. Hurried working will disturb the molecular grouping of the alloy; it will at the same time be heated and therefore softened, thus losing all the good qualities that are anticipated from hammer-hardening, namely increased body and elasticity. It was in order to avoid this heating that the old watchmakers used to hammer the brass in cold water, an excellent precaution which is too much neglected at the present day.

Brass that is badly hammered, the blows being violent or irregular, will spring out of shape on being cut and occasionally crack when gilding.

If during the process of hammering, a crack is observed to be commencing at the edge, it must be removed with a rat-tail file, all sharp angles being rounded off; and when cracks immediately reappear on continuing the operation, it is an indication that the metal cannot support any further hammering cold.

If brass is compact or well forged it may be relied upon to preserve the oil at pivots, etc., better, as oil is decomposed more rapidly in presence of a finely divided metal.

=104.= =Brass rods.= Rods having a square section must only be hammered on two opposite faces.

A rod of square section can be hammered on all four faces but it must be first filed perfectly square; the hammering must not be pushed too far, and the four angles must be maintained right angles. If some are made obtuse and others acute, a flaw will be produced in the direction of a diagonal.

The three following methods are employed in the case of round rods:

The first consists in hammering over the entire surface, the rod being at the same time rotated on the anvil by hand; but this operation must not be much prolonged, as the metal is liable to crack lengthwise.

The second method consists in reducing the diameter of an annealed brass rod to about one-half or two-thirds its initial amount by causing it to pass in succession through a number of holes of the draw-plate.

When the third method, which is due to Brocot, is adopted, one extremity of the brass rod is gripped in the bench vise and the other end in a hand vise, which is then caused to rotate round the rod as an axis. If the torsion be continued until the metal is on the point of breaking, it will be found to be very effectually hardened. This method is resorted to with advantage for hardening pin-wire and the metal for making pillars.

TO ANNEAL BRASS.

=105.= When it is necessary to considerably reduce the dimensions of a piece of brass, either with the hammer, rolls or draw-plate, it must be annealed from time to time.

The metal should not be heated to redness; it is supposed, rightly or wrongly, that such a proceedings especially if repeated, separates a portion of the zinc, or at least changes the mode in which it is associated with the copper. Brass should be heated slowly and uniformly, in a moderate fire, until the temperature is such that drops of water thrown onto the surface are rapidly converted into vapour, or paper turns yellow and begins to smoke. It is then withdrawn from the fire and allowed to cool.

Brass is brittle when hot, so that it can only be worked cold.

When brass is annealed, just as when steel is tempered, the metal should not be allowed to rest on a bad conductor of heat, such as wood or stone, because there will be a tendency to uneven distribution of the heat throughout the metal.

CAST BRASS.

=106.= This is usually brittle, owing to the fact that the copper employed in its manufacture consists, as a rule, of all sorts of scrap, from good or bad metal; moreover, from motives of economy, the proportion of zinc is generally increased and, in pouring, the precautions essential to avoid the effects of liquation (=102=), etc., are frequently neglected. Such an alloy must never be used for small objects, it must be entirely excluded from a watch, and in a clock only such pivots as are called upon to perform an insignificant amount of work should be allowed to run in it.

In order to avoid injuring the file, or embedding in the metal any particles of the hard coating of oxide that always covers rough castings, it is usual to dip the object in dilute nitric or sulphuric acid (=155=), by which the oxide is dissolved.

TIN.

=107.= This is an elementary body, almost as white as silver and having a breaking strain of only 8 kilo. per sq. mm. of section (or 11,300 lbs. per sq. inch.)

Watchmakers use it in making solder. It is also sometimes used in the form of plates or rods for polishing with rouge, and it is said to be much more efficient when very pure.

If a strip of pure tin is bent, a crackling noise, termed the “crying” of tin, is heard. After frequent bending, the metal loses this property.

The degree of purity may be judged:

(1) By the loudness of the “cry,” which is found to be greater as the tin is purer;

(2) By the relative lightness of two balls of equal size, one of which is formed of very pure tin and used as a standard;

(3) By pouring the metal, when just melted, in a mould 1 or 2 centimetres (about ¾ inch) in diameter. If tin is pure, when cast into plates or ingots, the surface will be perfectly smooth, without exhibiting any sign of crystallization at the moment of solidification, whereas the presence of small quantities of foreign metals causes it to be covered with a network of needle-formed crystals, which are the more numerous according as the metal is less pure.

The Banca tin is almost chemically pure; English tin is also very pure; but others contain a small percentage of copper, lead, iron, or arsenic.

BRONZE.

=108.= Bronze is an alloy, in very variable proportions, of copper and tin, to which may be added, according to circumstances, a small percentage of lead or zinc, or even iron, when it is desired to increase the hardness or tenacity.

As a rule, this alloy is tough and hard to work; it is especially used for parts of large machines that are subjected to considerable pressure.

The fusion and casting of bronze require special precautions, for the proportion between the metals is liable to vary through oxidation of the tin, which then goes to form a dross, and the composition may vary throughout the mass. It sometimes results from this that the bronze bearings for the pivots in large clocks are not even as good as ordinary brass, and wear away more rapidly than the pivots.

Bronze is also used by watchmakers for making plates or small rods for polishers, and for the bells of clocks. Bell-metal contains about 78 per cent. of copper and 22 per cent. of tin; it has a beautiful fracture, and is very fusible and sonorous. The addition of any other metal is rather prejudicial than otherwise; this explains why so many clock bells are wanting in sonorousness.

An impediment to the use of bronze is its want of malleability; but Dronier has recently pointed out that such alloys may be rendered perfectly ductile and malleable by adding from ½ to 2 per cent. of mercury. These alloys are said to be less oxidizable than ordinary bronzes, and at the same time more hard, elastic, resisting and sonorous.

STERRO.

=109.= This is an alloy containing 56 per cent copper, 41 zinc, 2 tin and 1 iron. It resembles a reddish-colored brass, and has been much used in Vienna, where it is considered superior to brass from the point of view of ductility, tenacity and malleability.

An experienced horologist, M. Grossmann, made satisfactory lever escape-wheels of it, and he considers it to be superior to the best brass in regard to both density and elasticity. At the same time he points out that it clogs the cutter, and the color is inferior to that of good hard brass.

LEAD.

=110.= A metal with a brilliant bluish grey lustre, which rapidly becomes dull when exposed to the air. It is very malleable and ductile. It breaks with a strain of 2.9 kilo. per sq. mm. section (4,000 lbs. per sq. inch), but possesses extreme flexibility.

Lead is not used in horology, except as a constituent of solders; in these, however, it plays a very important part. It is occasionally used in the pure state as a lap for applying polishing materials, but more frequently alloyed with tin, by which hardness is imparted to the metal, the alloy being known as “pewter.”

NICKEL.

=111.= An elementary metallic body of a greyish-white color, resembling that of platinum. With care it can be forged when hot and formed into plates; its structure in that case is fibrous. Its hardness is the same as that of iron, and nickel will take a high polish. Next to iron, it is the most powerfully magnetic of all metals.

It can be caused to alloy with many other metals—notably iron, cobalt, copper, zinc, tin, and antimony. According to Stodart and Faraday, an alloy of 33 parts iron and 1 part nickel is as malleable as the former metal, but less liable to rust. Fleitmann has recently shown that by the addition of about 1-10th per cent of magnesium, nickel is rendered perfectly malleable and ductile, capable of being drawn into wires or rolled into sheets, and Garnier finds that 3-10ths per cent of phosphorus has a similar effect.

Nickel is useful as a coating for objects that are not subjected to friction, for preserving them from the action of the air. It takes a beautiful polish, and is not tarnished by being touched.

GERMAN SILVER.

=112.= Although the proportion of copper in this alloy is considerably greater than that of nickel, watchmakers frequently apply the latter name to it, doubtless on account of the beautiful polish of which the metal is capable and the comparative inoxidizability which it derives from the presence of nickel.

German silver is an alloy of copper, nickel and zinc, with the occasional admixture of a small proportion of iron or tin. When used in the construction of objects that require soldering, 2 per cent. of lead is added.

The alloy usually employed in horology is very malleable; it has a mean composition: copper, 60 per cent; nickel, 20 per cent; and zinc, 20 per cent. That containing 58 per cent copper, 14 nickel, 25 zinc, and 3 iron, is said to be highly elastic.

The following useful details with regard to the employment of German silver for watchwork are due to M. C. E. Jacot.

Watch movements have been made of this alloy for the past thirty years; it was long thought that the taste would die out, but, on the other hand, the demand for “nickel” movements increases each year.

The alloy is better prepared at the present day; it has a beautiful grayish-white colour, it is more malleable, and better to work than formerly, but still not so easy as brass. The latter alloy is less detrimental to the file, and can be turned and drilled more rapidly.

German silver is only used for the plates, cocks and bars. The barrels and wheels are of brass, and surfaces exposed to friction, such as the center pivot-hole (all other holes being jewelled) are bushed with the same metal, for it is observed that in presence of nickel oil is rapidly blackened and the pivots wear sooner than when working in good brass.

The color remains unaltered for a long time if the surface has been carefully smoothed in the first instance; and if cleansed with soap and water, its original freshness can be to a great extent restored. Some watchmakers prefer to employ chemical preparations for cleaning the metal.

The following is recommended as very effective for this purpose: Mix 50 parts alcohol, 1 part sulphuric, and one part nitric acid. Allow the pieces to remain in this liquid for 10 or 15 seconds, wash with cold water, and subsequently with alcohol, dry with a soft rag or in boxwood saw dust.

GOLD.

=113.= An elementary body, the most beautiful and the most valuable of all the ordinary metals. In the unalloyed state it has a pure yellow color, and when reduced to extremely thin leaves, appears green by transmitted light. It is the most malleable and ductile of all the metals, but its tenacity is low.

Gold resembles platinum, silver, iron, etc., in being capable of welding, that is to say, two pieces of the metal can be united without previous fusion. Indeed, by the application of great pressure it can be made to weld when cold.

It is insoluble except in aqua regia (a mixture of 1 part nitric acid and 4 parts hydrochloric acid), alkaline persulphides and selenic acid. Chlorine, phosphorus, and a few other substances can be made to combine with it by the acid of heat.

It is as a preservative, that is applied in layers termed “gilding,” that gold is principally used in watchwork, and some details will be found on this subject under “Gilding,” (articles =142=-=153=). Owing to its softness the metal is not used in a pure state, but usually alloyed with copper. The principal alloys in use in this country are:

22 parts (carats) gold, 2 parts (carats) copper, for coin and wedding rings.

18 parts gold, 6 parts copper, for high-class jewelry and watch-cases.

15 parts gold, 9 parts copper, for ordinary jewelry.

12 parts gold, 12 parts copper; and 9 parts gold, 15 parts copper, for common jewelry.

The alloys used for soldering gold will be described under “Solders” (=126=).

Alloys of gold with silver and copper have been employed for making watch wheels; they wear well, and will take a beautiful polish, which is maintained for a longer time than in the case of brass wheels.

Chronometer balance-springs and the suspension-springs for astronomical clocks have also been made of gold-copper or gold-silver alloys rolled and hardened (=591=.) If carefully prepared, they maintain their elasticity unimpaired for a long period, and there is no liability to rust.

The dilatation for a given change of temperature is, however, greater than that of steel, so that a greater compensating effect becomes necessary, but this inconvenience is partially compensated for by its inoxidizability and the fact that it is not liable to become magnetic.

SILVER.

=114.= This metal in an unalloyed state is too soft for use in horology; its principal use is for cases, and as a constituent of solders.

Houriet made watch wheels of an alloy containing 2 parts silver to 1 part 18-carat gold, and he affirmed that this alloy became polished at the acting surfaces of the teeth. Jurgensen states that chronometer escape-wheels made of this alloy, carefully hammered, do not require oil at the points of their teeth.

Dumesnil proposed an alloy of 2 parts copper, 1 part silver, and 1 part zinc, all perfectly pure. Lecocq made chronometer balances in which the brass was replaced by pure silver deposited on the surface of the steel by electrolysis, thus avoiding the use of a fire. The compensation is said to have been very efficient.

ALUMINIUM AND ALUMINIUM BRONZE.

=115.= Aluminium is an extremely light elementary body, having a density of only 2.56; with equal bulks, therefore, it will weigh only about as quarter as much as silver. As its capacity for heat is very great, this metal is observed to heat or cool more slowly than other metals.

Pure, or in a slightly alloyed state, it has not been used in horology, except for pendulum rods and large hands in regulator clocks; in short, it can be employed where lightness is the principal quality in view.

It is extremely ductile. The presence of 1-100th part of bismuth, however, renders the metal somewhat brittle, and it develops cracks under the hammer. Traces of iron also decrease its malleability.

An alloy of 5 parts silver and 95 aluminium can be as easily worked as the pure metal, but is harder and takes a better polish.

We would add a curious observation of M. Redier: After passing a piece of aluminium several times through the draw-plate, he observed that the elongation had only occurred at the surface; for on cutting the wire at different points, he noticed that, throughout a portion of the length, the metal was hollow, a very fine capillary tube being thus formed.

=116.= _Aluminium Bronze_ is an alloy of aluminium with copper. A alloy of 5 parts of the former to 95 of the latter has a beautiful golden color, but if the proportion is changed to 10 and 90 parts respectively, we obtain the most serviceable and the most easily worked alloy.

This bronze can be forged at a cherry-red heat, and even near its melting point; and its thickness can be reduced to a very small amount under the hammer. It is easily filed and turned, but does not possess any special advantage over brass, which is less detrimental to the file; the density is 7.7, very little below that of brass, 8.4.

It appears from a considerable number of experiments that it might be used with advantage for the bearings of axes that rotate with high velocities. It resists wear better than any other metal. In the experiments made by Foucault to demonstrate the rotation of the earth by means of the pendulum, he found that an aluminum bronze wire lasted for the longest period. Its tenacity is equal to that of iron. It has been shown that slide-bars of locomotives made of this bronze resist wear twice as long as those formed of the ordinary bronze. There would then be an advantage in using it for the bearings of foot-lathes, etc.

Grossman asserts that lever escape-wheels of this metal have proved satisfactory, and he makes the following observation on the subject. If aluminium bronze be reduced to three-fourths of its original thickness by hammering, it will begin to crack. This can be prevented by heating to a red heat and plunging into water; it can then be again reduced by one-fourth of its thickness, and again annealed, and so on. He reduced the thickness from 2.5 millimeter to 0.2 millimeter, and the metal resisted for a long period repeated flexures backwards and forwards; and he observes that no other metal, after being so much compressed, would possess the same marvellous degree of tenacity.

In order to obtain aluminium bronze of the best quality, the copper should be absolutely pure, and, in the manufacture, the alloy must be melted and forged two or three times in succession, as by this means the strength and tenacity are increased, and the

metal can be more easily worked.

The beautiful golden color possessed by certain of these bronzes when polished, has caused them to be used for cheap watch-cases, but they always tarnish at those parts that are not subject to daily wear.

MERCURY.

=117.= This is the only metal liquid at the ordinary temperature; it solidifies at -40° C. (-40° F.). It possesses a high metallic lustre, resembling silver, but with a slightly bluish tint, and does not oxidize at ordinary temperatures.

Mercury alloys with many other metals, forming amalgams, and as small a quantity as 1-40th per cent of lead suffices to entirely alter its character. The presence of such traces can be easily detected by the liquid wetting glass or china, and therefore forming a tail when a vessel containing it is tilted.

The commercial metal is rarely pure, but the greater portion of the lead, tin, bismuth or copper, by which it is contaminated, can be removed by distillation. The most convenient method consists, however, in agitating the metal with either dilute nitric acid, a solution of mercurous nitrate, strong sulphuric acid, a solution of corrosive sublimate or of perchloride of iron, and subsequent washing with distilled water. When mercury is only contaminated with mechanical impurities, they can be very effectually removed by agitating with powdered loaf sugar.

This metal has many uses in the arts, for the construction of thermometers, barometers; for plating, etc.; in horology it is used for compensation pendulums, and has also been occasionally used for compensation balances.

PLATINUM.

=118.= This elementary body is almost as white as silver, takes a brilliant polish, and is highly ductile and malleable. It is the heaviest of the ordinary metals, the least expansive when heated, and has a breaking strain of 40 kilo. per sq. mm. section (56,500 lbs. per sq. inch.).

Platinum is infusible, except at the high temperatures attainable with the oxy-hydrogen blow-pipe. At a white heat, however, it softens, and can be forged and welded. It is unacted upon by the air at any temperature, and is insoluble in acids, except aqua regia (=155=), although acted on by certain alkalies.

This metal is used in the construction of scientific instruments, and for objects that are exposed to the air, as, for example, sun dials. Alloyed with irridium, (a rare metal of the same group) it possesses an excellent and unalterable surface for fine engraving, as the scales of astronomical instruments, etc. This alloy has also been adopted for the construction of international standards of length and weight.

Platinum is much employed for chemical apparatus, in consequence of its being unacted on by acids, and its non-liability to melt in ordinary furnaces. Both the pure metal and its alloys with silver have been employed in the form of wire for bushing the pivot-holes of watches, and in sheets for cutting out cocks and wheels, but the results obtained were not as good as with good brass. As a rule, such wheels are found to occasion a rapid wear of pinion leaves.

Attempts have also been made to construct balance-springs of this metal, but we are informed that they were not found to possess any sufficient advantages.

It is advisable to heat platinum in a spirit lamp or Bunsen burner; the naked flame is objectionable, because, being charged with a certain amount of carbon, it deteriorates the metal.

PALLADIUM.

=119.= This metal resembles silver rather than platinum, and is almost as infusible as the latter metal. It has a density of 12.5. When heated in contact with air it becomes blue, owing to the formation of an oxide. It possesses the remarkable power of absorbing (or _occluding_) about 900 times its own volume of hydrogen, if attached to the negative pole of a battery in acidulated water; its bulk is increased slightly by this charge, and, on expelling the gas by the aid of heat, the metal shrinks to less than its initial dimensions. Palladium is useful for the graduated scales of scientific instruments, since it is not discolored by sulphurous acid. It forms alloys with most of the metals and some of these can be hardened like steel. If 100 parts of steel be alloyed with 1

part of this metal, the resulting alloy is said to be excellent for making scientific instruments, and an alloy of 24 parts palladium, 44 silver, 72 gold, and 92 copper has been recommended for use in horology.

M. Paillard, of Geneva, has introduced balance-springs made of an alloy, whose composition is not given, possessing the following advantages: they are non-magnetic, their tenacity is considerable, are not tarnished by the air, sulphurous acid, or sea water; nor are they distorted by heating, and, on cooling, they recover their original elasticity, which is equal to that of steel hardened and tempered to a blue color. The co-efficient of expansion of this alloy is rather less than that of steel.

CHARACTERISTIC PROPERTIES OF ALLOYS.

=120.= _Density._ This is sometimes rather greater and sometimes less than that deduced from the densities of the constituent metals,[4] but no exact law has been discovered in regard to this question.

Hardness, Ductility, Tenacity. Alloys are usually harder, more brittle, and less ductile and tenacious than the most ductile and tenacious constituent metal.

Elasticity. The co-efficient of elasticity of an alloy generally approximates closely to the mean of the co-efficients of its constituent metals.

Expansion. The co-efficient of linear expansion of an alloy, that is to say, the number representing the proportional part of its length by which it increases for each degree rise of temperature, may be approximately estimated as follows: multiply the linear co-efficient of each constituent metal by the percentage of it present in the alloy, and divide by its density. Add together the several numbers thus obtained. Multiply this sum by the density of the alloy (which must be experimentally determined) and divide by 100. The resulting figure is the required linear co-efficient (=122=).

Fusibility. Alloys are always more fusible than the least fusible of their component metals, and often more so than any one of them.

Oxidation. As a rule, the air acts with less energy on alloys than on their constituent metals. There are, however, cases in which the converse is the case.

Action of acids. This is generally similar to the action on the predominating metal.

Observations. Alloys formed of metals that differ materially in density are rarely homogeneous, especially if they have been allowed to cool slowly. It is, then, essential that they be thoroughly stirred and cooled rapidly. It is for this reason that alloys are frequently poured out on to a flagstone to cool, or that they are compressed after pouring, whereby the formation of crystals is prevented.

=121.= =Metals and alloys.= The following table gives the more important physical properties of the metals and alloys generally met with, and will be found useful for reference. The precise meaning of each number may be gathered from the notes in paragraph =122=.

+------------------+------------+----------+----------------------+ | | Specific | Degree | Linear Expansion | | METALS. | Gravity. | of | per | | | (Water=1) | Hardness | 1° Fahr. 1° Cent. | +------------------+------------+----------+----------+-----------+ |Aluminium (115) | 2.56 | -- | 0.0000123 | 0.0000222 | | ” Bronze (116)| 7.7 | -- | -- | -- | |Brass, Drawn (101) | 8.54 | -- | 0.0000107 | 0.0000193 | | ” Cast (106) | 8.10 | -- | 0.0000104 | 0.0000187 | |Bronze (108) | 8.40 | -- | 0.0000100 | 0.0000180 | |Copper (99) | 8.94 | 2.5-3 | 0.0000102 | 0.0000183 | |German Silver (112)| -- | -- | -- | -- | |Gold (113) | 19.26 | 2.5-3 | 0.0000077 | 0.0000138 | |Iron, Wrought (54) | 7.84 | 4.5 | 0.0000066 | 0.0000119 | | ” Cast (58) | 6.9 to 7.5 | -- | 0.0000062 | 0.0000112 | |Lead (110) | 11.33 | 1.5 | 0.0000167 | 0.0000301 | |Mercury (117) | 15.60 | -- | 0.000101 | 0.000182 | |Nickel (111) | 8.82 | 5 | [cubical | [cubical | |Palladium (119) | 11.80 | 4.5-5 | -- | -- | |Platinum (118) | 21.50 | 4-4.5 | 0.000005 | 0.000009 | |Silver (114) | 10.57 | 2.5-3 | 0.0000111 | 0.0000190 | |Steel (60) | 7.72 | 6-7(hard)| 0.0000057 | 0.0000103 | |Sterro (109) | -- | -- | -- | -- | |Tin (107) | 7.30 | 2.5-3 | 0.0000152 | 0.0000273 | |Zinc (100) | 7.13 | 2 | 0.0000122 | 0.0000220 | +------------------+------------+----------+----------+-----------+

+------------------+---------------+---------+--------+------------+

=122.= =Notes on the foregoing table.= For a complete explanation of the several properties of metals and alloys that are enumerated in the above table, the reader must be referred to works on mechanics and physics, but the following explanatory notes are necessary.

The number in brackets after the name of each metal, etc., refers to the article in which it is considered.

The _specific gravity_ of a substance is the ratio of the weight of a given bulk of that substance to the weight of the same bulk of water at a definite temperature. The numbers here given can only be regarded as approximations, as the specific gravity varies greatly with the state in which a body exists, the hammering it may have been subjected to, etc.

Degree of hardness is ascertained by means of the following standard series, observing which of them scratches the body under examination and which it is capable of scratching.

1, Talc; 2, Gypsum; 3, Calc-spar; 4, Fluor-spar; 5, Apatite; 6, Felspar; 7, Quartz; 8, Topaz; 9, Sapphire; 10, Diamond.

Linear expansion. These co-efficients represent the extension in length that the several substances undergo when heated: the first column for each degree Fahrenheit and the second for each degree Centigrade. The extension is given per unit of length; thus, 1 inch of copper at 32° F. will become 1 + 0.0000102, or 1.0000102 inch at 33° F.; and 1 + 30 × .0000102, or 1.000306 at 32 + 30 or 62° F.

Superficial expansion may be obtained by multiplying the linear co-efficient by 2, and cubical expansion by multiplying the same number by 3.

As in the case of specific gravity, these data, as well as those in succeeding columns, can only be regarded as approximations, depending on the condition of the metal etc.

Specific heat is the amount of heat required to raise the temperature of a substance one degree (the Centigrade scale being here adopted), that required for the same weight of water being taken as unity. The corresponding numbers on the Fahrenheit scale can be deduced from those here given by multiplying by 5 and dividing by 9.

The _melting points_ are given on Fahrenheit’s scale and can only be regarded as approximate on account of the difficulty experienced in determining these high temperatures. Different observers often vary by two or three hundred degrees in their estimates.

Conductivity for heat and electricity are given in reference to that of silver, which is called 100. It surpasses all other known metals in both these properties when chemically pure, but a trace of impurity has a very prejudicial influence on them.

It will be observed that in many cases the conductivities have not been determined, a remark that applies to other columns of the table.

SOLDERING.

=123.= It is well known that a _solder_ is an alloy employed to unite, by the aid of heat, two metallic bodies that are placed in contact. A solder, then, must be much more fusible than the metals it unites, otherwise these latter would be damaged by the degree of heat applied. Solder is all the less tenacious, and melts the more easily according as the proportion of the most fusible metal present is increased.

This fact is taken advantage of when several solderings have to be performed on the same object. The alloy last employed will require to be considerably more fusible than the first, as otherwise the heat would be so great that the earlier joints would melt. In an ordinary lead-tin solder, the fusibility is increased by increasing the proportion of the latter metal till the lead is to tin, as 6 is to 1. This alloy melts at 194° C. (380° F.), and the melting point may be still further reduced by adding a gradually increasing proportion of bismuth.

As the melting point of the solder approximates to that of the metals to be united, the risk of damaging these latter is of course increased, but, at the same time, the joint will be all the stronger, as the metal will be almost as strong there as at any other point, and it can be forged, etc.

Solders are distinguished as _hard_ or _soft_; the former requires the application of a red heat, and can therefore only be used for such metals as gold, silver, brass; whereas the latter melt at very low temperature, and can be employed for metals that have low melting points, or when it is important not to exceed a moderate degree of heat. The joint is, however, the more solid according as the heat employed approximates to that at which the metal will melt.

=124.= =Composition of solders.= The solders ordinarily employed can be obtained from material dealers, but it is advisable to give here the composition of some of the more important, specifying the metal to which they are applicable.

=125.= _Aluminium solders._ I. Zinc, 70 parts; copper, 15; aluminium, 15.

II. M. Mourey employes a series of aluminium-zinc alloys, commencing with two per cent aluminium to 98 per cent zinc, and progressing to 20 per cent of the former to 80 per cent of the latter metal.

=126.= _Gold solders._ I. Gold, 6 parts; copper, 1 part; silver, 2 parts.

II. Gold, 15 parts; silver, 2 parts; copper, 1 part.

III. Gold, 11.94 parts; silver, 54.74 parts; copper, 28.17 parts; zinc, 5.81 parts. The three first metals are melted together in a crucible, and when they have somewhat cooled, a rather greater proportion of zinc than is here indicated (to allow for loss by volatilization) is added, and the alloy constantly stirred.

=127.= _Silver solders._ I. Silver, 2 parts; brass (for pin-wire), 1 part.

II. Silver, 5 parts; pin-wire brass, 1 part.

III. Silver, 10 parts; pin-wire brass, 5 parts; pure zinc, 1 part.

=128.= _Tin solders._ I. (ordinary soft solder.) Tin, 2 parts; lead, 1 part.

II. (Harder, and known as “Plumbers’ Sealed” solder.) Tin, 1 part; lead, 2 parts.

III. Many other proportions of tin and lead are occasionally used, ranging from tin, 1 part; lead, 25 parts, to tin, 6 parts; lead, 1 part.

IV. (Very fusible solder, melting in boiling water.) Lead, 3 parts; tin, 5 parts; bismuth, 8 parts. The fusibility is still further increased by adding mercury or cadmium.

=129.= _Spelter solders._ (Used for brazing.) Copper and zinc in varying proportions. It becomes more fusible as the amount of zinc present is increased.

METHODS OF SOLDERING.

=130.= A thorough cleansing of the surfaces to be united is always needful, but more especially so in the case of soft soldering. It may be effected by means of acids, or with a graver or scraper, etc.; the cleansed surfaces must not be touched with the fingers, and the soldering should be done at once. If acids are employed, the objects should be thoroughly washed after soldering, in order to avoid rust; and, after drying, they should be rinsed with alcohol.

The parts to be soldered are held in position with clamps, tweezers, pins, or iron wire. This latter, known as _binding wire_, is used for delicate objects and should be very pliable. When a high degree of heat is to be applied, all risk of the iron uniting with gold may be avoided by mixing a little sandiver with the borax employed. (See article =153=).

Before heating, if there are already parts united with solder, they should be covered with borax to prevent softening.

Only a moderate heat should at first be applied, so as to melt the borax, or sal-ammoniac without displacing it. The violent frothing up, which is very liable to displace the parts or the fragments of solder, can thus in a great part be avoided. If a naked lamp-flame is

used, or if it is directed on to the object with a blow-pipe, it should be, so to speak, large and soft, and the jet should not be directed to the point of juncture until the solder is observed to have fused. In soldering brass to steel, it is sometimes necessary to direct the flame against the brass only, in order, as far as possible, to avoid softening the steel. The hard solders for gold, silver, etc., require a considerable degree of heat, so that the objects must be heated to redness.

=131.= =To solder gold and platinum= to each other or to themselves. On a hard wetted surface, marble, for example, rub a piece of borax until a white liquid paste is obtained (or the powdered borax sold by chemists can be made into paste direct). Having prepared the borax, the surfaces to be united are cleansed either by scraping or with dilute nitric acid (=155=); the acid may be previously heated to boiling, as it will then act more rapidly; and the surfaces are subsequently scraped. They are now covered with the borax with a paint brush, set in position, and small pieces of solder placed on the junction. As already observed, the heating must at first be gentle to avoid displacing the solder by the frothing of the borax.

=132.= =To solder silver.= Also for uniting gold to silver, or silver, brass, steel to each other or to themselves. Proceed in the manner already explained for gold and platinum, except that the borax paste must be sensibly thicker.

=133.= =To solder tin.= Also for uniting gold, silver, brass to each other, or to other metals, such as steel, iron, etc. Clean the surface with a graver or scraper; sulphuric or hydrochloric acid may be used, but in this case the cleansing afterwards must not be forgotten.

The heating is effected as in soldering gold, unless a soldering iron is used, when the directions subsequently given should be followed.

=134.= =To solder aluminium.= M. Mourey recommends the following method.

One of the series of aluminium solders, No. II. (art. =125=), is employed and, as a flux, two-thirds of balsam of copaiba, one-third very pure Venice turpentine, and a few drops of the juice of a citron; these constituents are pounded together in order to secure a perfect admixture.

The surfaces to be united are covered with solder (employing a soldering iron of aluminium) just as in the case of tinning (=137=), the flux just mentioned being used. The two surfaces, thus prepared, are placed in contact and maintained in the required position, and, after laying on the joint particles of solder that are richer in aluminium than the one used for preparing the surfaces, the whole is placed over a charcoal fire or heated before the blow-pipe, pressing gently on the pieces of solder, which will soon melt and should be distributed by means of a little tool of aluminium.

During this second stage of the process, it is necessary to be very cautious in the application of the flux; the pieces of solder should only be dipped in it before being placed in position, for the flux is mainly for use in preparing the surfaces; as soon as the solder has run well, the temperature should be lowered in order not to dry up and burn the solder, which would be apt to become brittle.

In preparing the solders, the aluminium is first fused and stirred with a small iron rod; then add the zinc and stir again; add a little tallow and cast the solder into rods.

The zinc must not be too much heated, as it will volatilize, leaving the alloy rich in aluminium and therefore brittle.

=135.= =Fluxes for soldering.= Various substances can be employed as fluxes for cleansing the surfaces to be united:

Sal-ammoniac reduced to powder and made into a paste with sweet oil, or merely dissolved in water. A paste formed of _sal-ammoniac_ and _resin_, reduced to powder, with water or oil. _Resin_ alone will suffice for the soft soldering of copper or brass. _Venice turpentine_, which has the advantage of not causing steel to rust, although it makes the objects sticky so that they require to be afterwards rinsed in alcohol or turpentine.

Various acid solutions are sold for the purpose and experience will enable the watchmaker to select that which is best adapted to his requirements.

Lastly, saturated _chloride of zinc_ can be recommended. It is prepared as follows:

Some dilute hydrochloric acid (which also goes by the name of spirits of salts, or muriatic acid) is placed in a glass flask and strips of zinc are added one by one; the flask must be left uncorked and the zinc added a little at a time, lest the effervescence that occurs

should break the vessel. When the zinc added is not acted on by the fluid it may be concluded that the acid is saturated or “killed,” and the fluid may then be transferred to a stoppered or corked bottle for use. In using it, a small quantity is spread over the surfaces that are to be united and the solder will be found to run with great freedom. Some authorities recommend the addition of sal-ammoniac to the extent of one-fourth the weight of acid taken. It is well again to warn the reader that the pieces must be thoroughly washed after employing these liquids, for, otherwise, they will cause tools with which they are brought in contact to rust and will rust themselves if they consist wholly or in part of iron or steel. The vessel containing the fluid must be kept well away from the work-bench.

The liquid can be used immediately after being prepared as above explained; but all acid reaction may be prevented by evaporating at a moderate temperature until of the consistency of oil; it is then allowed to cool and kept in a bottle.

=136.= =The soldering iron= with a head of copper, such as is used by tin-plate workers, is well known; if made on a small scale it may occasionally be of service to the watchmaker. The tool may be =T=-shaped, one end of the horizontal portion, the copper head, terminating in a rather thin blade, and the other enlarged, so that, when held in the flame of a lamp, it will store up a sufficient amount of heat. The upright part of the =T= corresponds, of course, to the handle. After the iron has been heated just short of redness in the dark, the end of the blade is moistened with soldering fluid and a small piece of solder attached to it. The object to be united is gently heated and also moistened with the fluid; the iron charged with solder is presented to it, often with the enlarged extremity of the head maintained in the flame of a lamp, and the solder will, as a rule, run without again heating the object, although this might be done while the iron is still in contact. It may be found convenient to fix the iron in a suitable position with the lamp below the large end of the head; the object will then be brought against the iron after being moistened with the fluid.

=137.= It is often advisable to tin the surfaces to be united previous to soldering them; in order to do this they are moistened with soldering fluid, small pieces of solder are then spread over, and these are fused by passing the hot iron over the surface; or the solder can be spread after fusion by means of a metallic rod charged with the liquid.

=138.= =Brazing.= This operation consists in soldering iron, steel, brass, or copper, with an easily fusible brass, which is specially prepared in the form of coarse dust, termed spelter solder, or cut in thin strips of convenient shape (=129=). The method resembles, in all essential particulars, the application of hard solders previously referred to (=131=, etc.)

Heat is usually applied direct by the blow-pipe, borax being used as a flux, and the precautions taken that are mentioned in article =130=: it is necessary to avoid a greater degree of heat than would melt the brass, since the object might in that case be fused. For fine work, it is better to employ silver solder.

On an emergency, two pieces of steel can be united by brazing and subsequently hardened, and we have successfully practiced this method in such a case as the following: A small portion having been broken off from the quarter-piece of a repeater, we dovetailed into it another piece of steel of the required form, but a trifle too large at the upper side. When the brass had run well into the joint, and the piece was still at a full cherry-red heat, it was hardened, and afterwards cleaned and tempered to a blue color. The upper surface was then brought to shape with a good file, resting it on a wooden block against a projection, and, after making sure that it would act correctly, the whole was smoothed and polished. It has since worked well and does not show signs of wear.

BRONZING.

=139.= =To bronze copper.= The following are two methods recommended for bronzing objects of this metal, for example, a medal.

Dissolve two parts of verdigris (acetate of copper) and one part of sal-ammoniac in vinegar. Boil the solution, skim it, and dilute with water until it no longer possesses a feebly metallic smell, nor produces a whitish precipitate on the addition of water. Then let it boil again in an earthenware or porcelain vessel and transfer it, while boiling, into another vessel containing the perfectly clean medals, etc., and place the whole on the fire. As soon as the medals assume the required color, remove them, and wash carefully in clean water.

The objects must not be left too long in the acid bath over the fire, because the layer of oxide would become too thick, and would easily scale off the surface; whereas, if the operation is properly conducted, the coating adheres so firmly that it cannot be separated even by scraping. Of course, it is only after a certain number of trials, and with experience, that the exact moment can be ascertained for removing the objects from the bath. It is very necessary that the bath be not too concentrated, as the superficial oxide becomes proportionately less adherent: moreover, a whitish powder is deposited on the medal, which turns green on

exposure to the air and spoils the appearance of the bronzing.

=140.= =Chinese bronzing.= The Chinese employ the following mixture for bronzing copper, the several constituents being powdered before being incorporated together: 2 parts of verdigris, 2 parts of cinnabar, 5 of sal-ammoniac, 5 of alum, and 2 parts of the beak and of the liver of a duck. A paste having been made, with vinegar, it is spread over the perfectly clean surface of the copper, and the whole exposed for an instant to the fire, then allowed to cool, washed, and the operation repeated as often as may be needed in order to obtain the desired tint.

By adding sulphate of copper to the mixture a browner shade will be obtained, and it may be made yellower by adding borax. Copper thus treated is said to present a beautiful appearance, and to be so permanent that neither air nor water has any influence against it.

=141.= =To bronze brass.= Dissolve copper turnings in nitric acid until it is completely saturated. Immerse the brass objects to be bronzed in this solution after they have been cleaned, smoothed with water of Ayr stone, and heated to such a temperature as the hand can just support; on being placed over a charcoal fire they will assume a green color; rub them over with rags, repeat the immersion and heating over charcoal until the required tint is obtained. The shade may be improved by oiling the finished surfaces.

It is asserted that by immersing copper articles in molten sulphur containing lampblack in suspension, they assume the appearance of bronze; and that they may even be polished without losing their color.

GILDING.

=142.= =Gold gilding without the aid of mercury.= Prepare the gold in fine powder, as explained in the following paragraph, or procure it from the dealers in chemical products, who manufacture it of various tints. Make a mixture of this powder with pure rock salt and cream of tartar (bitartrate of potash), pulverized in the same manner as described in speaking of silver-plating and take the same precautions in its application.

The gold surface will present a dull appearance; acid cannot be used to improve its color when operating, for example, on a wheel with attached pinion, but the same result may be attained by a very simple method. Rub the object after plating with cream of tartar, mixed with a large proportion of water; then immediately wash in an abundance of warm water at not less than 40° C. (104° F.); soap it thoroughly, so as to neutralize any acid that may remain, and finally pass through alcohol to dissolve any remaining soap.

The surface will be still further improved by rubbing with a very hard piece of pith, such as is occasionally met with.

M. Robert, in describing the above method, adds: “In this manner I have gilded cocks, domes, compensation balance weights, and even their brass rims. When, skilfully and expeditiously performed, the pinion need not be discolored; but, if it is at any time slightly marked, it may be restored by at once rubbing the surface with a soft stick and fine rouge.”

=143.= =Preparation of the gold powder.= As already observed this can be obtained of any desired color from the dealers in chemical products, but the following method is given for the benefit of any one who desires to prepare it for himself:

Place some gold in thin leaves in a dish, and add a little honey, thoroughly intermixing the two by the aid of a glass rod flattened at one end; then place the paste so obtained in a glass of water containing a little alcohol, washing it and allowing the powder to settle. Decant the liquid and again wash the residue, repeating the operation until a fine brilliant powder is obtained. This powder is mixed as required with rock salt and powdered cream of tartar in the manner already described.

=144.= _Second method._ Dissolve one part by weight (say about ten grains) of pure gold, rolled very thin, in aqua regia (=155=) contained in a porcelain dish, which may be gently heated on a sand-bath, and evaporate the acid until it assumes a blood-red color. Add about 30 parts, by weight, of warm distilled water, in which 4 parts of crystallized cyanide of potassium have been previously dissolved; thoroughly stir the mixture with a glass rod, and filter it through a glass funnel.

=145.= _Third Method._ Roseleur recommends the following solution for gilding by simple immersion. Distilled water, 17 pints; pyrophosphate of soda (in crystals) 28 ounces; hydrocyanic acid, 1-3 ounce; crystallized perchloride of gold, 2-3 ounce. The pyrophosphate is added, in small quantities at a time, to 16 pints of water, in a porcelain vessel, stirring with a glass rod and applying gentle heat; then filter and cool. The gold salt is dissolved in a small amount of water; filter and add to the cold solution of pyrophosphate; lastly, add the hydrocyanic acid and the solution, heated to the boiling point, is ready for use.

The articles to be dipped must be thoroughly cleansed and passed through a very dilute solution of nitrate of binoxide of mercury; they must be constantly agitated while in the bath and the best coating is obtained by dipping the articles in a nearly exhausted solution of the same kind immediately after the mercury solution.

=146.= =Electro Gilding.= But the method most usually adopted is that in which a battery is employed. It is, however, impossible, within the limits of this work, to explain the precautions that are necessary in conducting the process, managing the battery, etc., and the reader must be referred to works on electro-metallurgy for these details.

=147.= =To prepare the pieces to be plated.= After the surface has been stoned, boil the object a few minutes in a solution of soda or potash, and rinse in clean water.

Roseleur, in the articles already referred to, gives very full instructions, of which the following is an outline. The reader who desires to obtain more complete information can consult his works.

Attach the pieces to a cork and brush with a clean brush charged with water and pumice-stone powder and thoroughly rinse. Place them in a solution consisting of: water, 2¼ gal.; nitrate of binoxide of mercury, 1-14 oz.; sulphuric acid 1-7 oz. Then rinse again.

=148.= =Graining.= Mix thoroughly with the application of moderate heat, silver powder, 1 ounce; pure common salt, finely powdered, 13 ounces; cream of tartar 4 to 5 ounces. Make a thin paste of this mixture with water and spread with a spatula on the pieces; having mounted them on a cork to which a rotary motion is given, rub them in all directions with a brush with close bristles, adding fresh paste from time to time. When the desired grain is obtained, wash and scratch-brush with revolving wire brushes. Three of these are often used of varying degrees of hardness and a decoction of liqorice, weak size or stale beer is liberally applied to the surface.

=149.= =Resist.= This is a composition for covering steel parts in order to protect them from the action of the acids, etc., in the various processes of cleaning, graining and gilding. It consists of yellow wax, 2 ounces; clear resin, 3■ ounces; very fine red sealing-wax, 1½ ounces; finest rouge, 1 ounce; Melt the resin and sealing-wax in a porcelain dish, then add the yellow wax, and when the whole is thoroughly liquid, gradually add the rouge, stirring with a glass rod. The parts to be coated are slightly heated and covered with the mixture.

To remove the resist after the gilding process is completed, place the pieces in warm oil or turpentine, then in a very hot soapy or alkaline solution and lastly in fresh water.

=150.= When prepared as above explained, the object may be gilt by one of the preceding methods; of course a hot solution cannot be resorted to when the resist has been applied.

=151.= =To clean objects that are of gold or gilt.= The following method is equally applicable to pieces that are gilt, such as cocks, domes, etc., the frames and parts of timepieces and to either gold or gilt jewelry.

To about a tumbler of water add 20 drops of strong ammonia. Immerse the object several times in this mixture and brush it with a soft brush; as soon as the operation appears to be completed (which experience will soon enable the workman to ascertain), wash in pure water, then in alcohol, and dry with a fine linen rag. The original brilliancy of the gilding will then be restored.

When the coating is thin and has been galvanically deposited, only very soft brushes must be used.

Gilders, instead of dipping in alcohol and drying with a linen rag, usually immerse the pieces in boxwood sawdust, leaving them long enough to become thoroughly dry; after this treatment they merely require to be shaken and lightly rubbed with a fine brush.

The sawdust must be perfectly dry; indeed it is a good plan to slightly warm it by placing the wooden box containing it for a few minutes on a hot oven or stove in the winter and exposing it to a hot sun in summer.

Instead of ammonia, alum (=156=) is sometimes boiled in water and the objects dipped two or three times in this solution, subsequently brushing as in the previous case.

=152.= _To restore the dead surface of gold or gilt objects._ Place them for two or three minutes in chlorine water, rinse them in clean water, soap them and finally dry in sawdust. It is advisable that parts that are polished be prevented from actual contact with

the liquid as it would produce a somewhat deadened surface.

=153.= _To clean gold jewelry after soldering._ Particles of binding wire are often left adhering to the surface of jewelry after soldering, and, on dipping the object into the dipping liquid, a layer of oxide may be formed. This can be removed without detriment to the polished surface by plunging the object for a few seconds in nitric acid (=155=).

ACIDS AND SALTS.

=154.= The watchmaker has occasion to employ a few acids and salts. He should never forget the advice already given to keep them away from his work-bench and always to well wash a piece of metal that has been in contact with them.

=155.= =Acids.= _Nitric Acid_, either in a concentrated or dilute form, will dissolve iron, steel, copper, lead, silver, zinc, brass, nickel, mercury, German silver. It does not dissolve tin, but reduces it to a white powder, known as metastannic acid. Hence, if an attempt be made to dissolve bronze which contains tin, this metal is deposited, and the copper and zinc pass into solution.

Sulphuric acid will dissolve iron, steel, copper, tin, silver, zinc, brass, nickel, mercury, German silver.

Hydrochloric acid will dissolve iron, steel, zinc and nickel and has a slow action on copper, tin, brass and German silver.

Aqua regia, a mixture of about 2 parts hydrochloric and 1 part nitric acid, will dissolve all the above-named metals, and in addition, gold and platinum, although separately neither acid will attack these metals.

Hydrofluoric acid attacks and dissolves all metals, except platinum, lead and silver with violent effervescence. It is also used for etching on glass or enamel. It is usually preserved in gutta-percha bottles, and is of such a dangerous nature that no use should be made of it without a good knowledge of its properties.

Acids are rarely employed pure by watchmakers; they are diluted with water. Nitric acid of commerce has a density of about 1.4 (38° on Baume's hydrometer). If this density is reduced by the addition of water to 1.16 (20° Baume), we obtain the acid most commonly employed. For cleaning metallic surfaces prior to soldering etc.; for giving a grained surface to brass, and for whitening blue steel, special proportions are found most convenient, which the reader can best determine experimentally for himself, remembering that the action of the acid should neither be too quick nor too slow. When once he has ascertained the best proportion, he can always recover it by the aid of the hydrometer.

=156.= =Salts.= _Borax_ serves as a flux in soldering gold, silver, platinum, etc., (=131=); also for the same purpose in brazing (=138=); it is met with in crystals or as a powder.

Sal-Ammoniac (also called _Chloride of ammonium_), is used for soldering tin, either as a powder or made into a paste, with sweet oil or with water, or mixed with resin.

Alum dissolved in water may occasionally be used in place of nitric acid for cleaning surfaces that have been soldered; it attacks iron or steel more energetically than copper, zinc, or brass. This fact is often taken advantage of for removing broken screws, etc., from brass plates. All other steel parts are removed and the plate placed in a solution of alum, when the steel screw is gradually eaten away by being converted into rust.

In 100 parts of cold water, only 9 parts of alum will dissolve, but if the water be boiled, it will take up 75 parts. Its action will then be proportionately more energetic when boiling.

OIL.

=157.= The oil intended for use as a lubricant for watchwork, etc., should be kept away from the light, as otherwise it would be discolored; it is on this account that the bottles containing such oil are frequently covered with black paper. Only the quantity wanted for immediate use should be placed in the oil-cup.

Two preliminary tests will afford some indication as to the quality of an oil. A thick layer is placed on a small portion of the surface of a glass plate, and side by side, a similar layer of another oil used for comparison, and they are exposed to the air for some time without being touched. The one that is found to be sticky under the finger when the other has dried up will, in all probability, be preferable. The second preliminary test is made on a whetstone; it is usually found that the oil that takes the longest time to thicken

is of better quality. Of course these tests will only suffice to afford a rough approximation, and cannot be accepted as conclusive.

The mode adopted for testing either the acidity or the purity of oil will afford no evidence as to how long it will maintain its fluidity; and very good results have at times been secured by the use of oils that were slightly acid, or from mixtures of oils of two or more qualities.

Many of the methods recommended for purifying oils are to a great extent illusory, for they cannot impart to the fluid characteristics that are wanting from the beginning. Success depends largely on the skill of the manipulator; and if he is not endowed with the power of judging, mainly by the taste, whether oil satisfies certain prescribed conditions, he can never be certain of the result. Crops differ as regards degree of maturity, etc., from year to year; and the animals from which oils are procured are rarely in the same condition as regards health, age, nourishment, etc.

Tests made on a whetstone, and on a window-pane, as well as observations made on drops of oil placed in jewel holes, or in oil-cups in a metal plate kept for the purpose—some of the drops being exposed to the air, while others are in closed boxes—will afford valuable indications; and according to the observations of M. H. Robert, it is safe to consider an oil bad if, at the end of six or eight days after being placed on a plate of good brass, it shows a marked green tinge—especially so if a clearly defined fringe forms round the drop, or else if the brass itself is discolored.

After all, the only evidence on which the watchmaker can rely is that which he obtains by experimenting on watches which he keeps to lend to his customers while their own are undergoing repair, and these trials should last for at least a year.

And there is great variety among the wearers of watches. Some live in constantly varying temperatures, often dusty; many ladies use perfumes; some persons perspire more than others; all these causes influence the oil, and make it alter or evaporate more rapidly in one watch than in another.

=158.= =To secure the maximum permanency in oil.= In the case of very many watchmakers who complain bitterly of the oils they employ, the fault is their own and not that of the oil; for they neglect the most simple precautions, both in purchasing and in using it.

The following are a few points to which attention should be given:

Do not buy, from motives of economy, bottles that have lain for years in the shop.

Keep the oil away from the light, and only take in the oil cup the amount required for immediate use, as stated above.

Ascertain that the watch-cases close well. If they do not, there will be air currents generated, and the oil will suffer.

The oil in a cylinder escapement will always deteriorate very rapidly; some watchmakers coat over the inside of the dome-joint and recommend the owner not to open it. By doing so, the oil can be maintained in good condition at the escapement for a long time.

Lastly, when cleaning a watch, the work should be conscientiously done. This point is very important.

When the parts are carelessly cleaned with soap, or with impure benzine, they will, after a few months, assume a dull colour, in consequence of a thin layer of the materials used in cleaning having been left on the surface. It has at times been noticed that steel work was preserved from rust through the perspiration of the wearer, after being cleaned by certain fluids. Evidently this was due to a thin coating having been left on the surface of the metal. The conclusion to be drawn is obvious: clean carefully; push the pivots into rather hard pith; finish with a soft brush in proper condition, and clear out all pivot-holes with pegwood.

=159.= =Mixed oils: camphorated oils.= Good results are frequently obtained by mixing together two different kinds of oil. Thus, American watch oil, which is very fluid and apt to evaporate at the temperature of the pocket, is improved by the addition of a somewhat thicker oil. A mixture of real American oil with the Rodanet oil has been recommended as excellent.

There are some who advocate the addition of a small quantity of camphor to an oil that is known to be satisfactory, but we cannot answer for it from personal experience.

=160.= =Sinks.= In cleaning, it is important to avoid removing the gilding in the oil sinks of watches, or the superficial oxide in the sinks of clocks that have been going for a considerable time. For if it be removed, there will be a fresh coating formed in time, and this, too, at the expense of the oil.

In new timepieces that are not gilt, it is well worth while polishing the sinks over their entire surface. If not applied too liberally, the oil will then be more likely to remain in contact with the end of the pivot. Moreover, as the surface is smoothed and hardened, and its pores are, as it were, closed by the action of the polisher, the oil will oxidize more slowly. This fact was first pointed out by Robin.

=161.= _Caution to be observed in applying oil._ The precautions to be observed in applying oil will be better considered in Part V. of this work, where we shall describe the method of cleaning and putting a watch together.

=162.= =Retention of oil on acting surfaces.= Since oil is essential in order to diminish friction, and the movement of the bodies to which it is applied tends to drive it from the surfaces of contact, it is important, with a view to its being constantly brought back and maintained in proximity to these surfaces, that they be formed in accordance with certain rules based on the laws of hydrostatics.

ALCOHOL.

=163.= Only what is known as rectified alcohol should be used in cleaning parts of watch work. The copper pan in which it is made to boil should not be too thin. The handle should be so arranged that it can be fixed in the vise, and the lamp held under the pan.

When, in heating, the alcohol ignites, it is best not to attempt its extinction by blowing; if the pan is held against the under side of the bench, the flame will at once be put out, or this can be effected by merely laying a piece of sheet metal over the pan. A good plan for preventing ignition is to make a lid of wire gauze, which is placed over the pan during the application of heat.

The substance known as “methylated spirit” is a cheap preparation of alcohol, and of use for burning in a spirit lamp, and for other purposes where the alcohol is not required to be pure.

BENZINE, ETC.

=164.= This and other preparations of a similar nature, such as Essence Lemoine, Essence Genevoise, etc., are much used for dissolving clogged oil and other substances of a greasy nature from parts of watches in cleaning.

POLISHING MATERIALS.

=165.= The following account of the materials used for polishing, is, for the most part, extracted from Holtzapffel’s _Turning and Mechanical Manipulation_, to which the reader is referred for fuller information in regard to them, and to their mode of application:

=Buff Leather= glued to a flat surface, or to the edge of a revolving disc, is used with emery, crocus, rottenstone and other powders.

=Charcoal= is much used by steel and copper-plate engravers. That made by burning elder without access of air is considered the best, but willow and elm have also been recommended.

=Diamond=, in the form of powder, is used by lapidaries, seal engravers, and watch jewel makers. The latter obtain the diamond _bort_ that is rubbed off stones in faceting, and they separate it into various degrees of fineness, by decantation (=168=). The mode of applying it is described in articles =207=, =216=.

=Diamantine=, Sapphirine, Rubitine, etc., are names given to various chemical preparations for polishing, to be obtained at the tool shops; they must not be assumed to consist in any way of the jewels from which their names are derived.

=Emery.= At the present day, oilstone dust is very frequently replaced by emery with oil or water, especially in clockwork. Any required degree of fineness can be obtained by decantation. Emery dust is sometimes used in place of rouge for polishing.

The solid emery wheels and sticks, that are now common in the trade, work rapidly, but they have the disadvantage of heating steel, and many of them soon become pasty. The heating renders them less suitable for grinding gravers, but they are very convenient for roughly shaping steel work, or removing the hard surface caused by the application of heat.

To make emery paper. If occasion requires it, this can be done as follows: Fix a sheet of stout rope manila paper on a board, glueing it round the edge. Having put emery powder into a sifter, the mesh of which has the requisite degree of fineness, and rapidly covered the surface of the paper with thin hot glue, shake the sifter lightly over the paper until it is evenly covered, and leave to cool. When dry, detach the paper and shake it vigorously to detach loose grains. Cloth may be used instead of paper, if desired.

=Hone slates.= Under this heading are included a great variety of stones used for smoothing and polishing.

Ayr stone, or water of Ayr stone, is much used for smoothing brass work prior to gilding (=142=), etc. It should be kept wet in order to prevent it from becoming hard.

Blue polishing stone is much used by jewelers, clockmakers, and others; it is recommended for use in spotting (=174=) and for polishing wheels (=176=.)

Oilstone. This forms the quickest cutting whetstone known. Oilstone slips are used by watchmakers after the manner of files. Oilstone powder, or dust, is much used in the earlier stages of polishing, and is preferable to emery in that it does not leave particles embedded in the surface of the metal. On pewter laps it may also be employed for polishing steel work.

Oxides of iron. Under this head are included the several materials known as crocus, rouge, red-stuff, colcothar of vitriol, etc. It is advisable to remove gritty particles from these materials by decantation (=168=) before using.

Pumice-Stone is extensively used for polishing cut glass, and is applicable to brass and other metal work.

Putty Powder is oxide of tin, or, more commonly, of tin and lead in varying proportions. The whitest kind, provided it be heavy, is considered the best.

Rottenstone. This variety of tripoli is of the greatest value for polishing brass work, as well as for silver, glass, and even the hardest stones.

Tripoli is of a greyish yellow or red color, and consists mainly of silica. Its principal use is in the polishing of hard woods.

Whiting is common chalk, ground, washed to remove sand, etc., and dried in lumps.

=166.= =Polishing Stones.= The following method is described by M. Cadot for preparing these stones, which are very useful for polishing a wheel that is not riveted to its pinion (see article =185=).

Carefully select a blue stone; after dressing its surface, smooth it with emery paper of gradually increasing fineness. Saturate the surface with oil, and rub it with a common piece of rough sapphire, one face of which is flat and partly smoothed, until the surface of the stone is hardened.

Such a stone is used dry. The wheels must previously have been carefully smoothed, since the stone does not abrade the metal. If care is taken to avoid scratches, the surface will last for a long time, although, of course, it is only serviceable for gold, brass, nickel or metals of a similar degree of hardness.

=167.= The several materials used for polishing must be kept carefully packed (glass stoppered bottles are preferable), as a few grains of dust, or of foreign bodies, will suffice to prevent the operation of polishing from being successful. Polishers should be filed very smooth, with a perfectly clean file that is not quite new. Files that are dirty or new will deposit small hard particles of dirt, or cause pieces off the points of their teeth to become embedded in the surface of the polisher.

PREPARATION OF POLISHING MATERIALS.

=168.= =Decantation.= This consists in causing a material in a fine state of sub-division to fall slowly through a liquid with the view to separate coarse particles, or various degrees of fineness, by taking advantage of their different rates of descent.

The watchmaker should prepare all his smoothing and polishing materials, etc., by decantation. He will by this means obtain them in grains that are much more uniform in size, of any required degree of fineness and free from hard or large particles.

[Illustration: _Fig. 40._]

The operation is exceedingly simple. The material having been pounded under the hammer or otherwise, is thrown into a vessel more or less filled with a liquid, water, oil, etc. After being thoroughly stirred, it is allowed to partially settle, and the liquid is carefully poured into another vessel. All the coarse heavy grains will be found as a residue in the first vessel; they are collected and used for coarse work. After again stirring and leaving to settle for a longer period, the liquid is again poured off, and the powder thus separated will be the second degree of fineness, so that it may be termed No. 2. By successive operations, in which a gradually increasing interval of time is allowed, Nos. 3, 4, etc., can be obtained; that is to say, a series of powders of the same material but presenting a greater degree of uniformity in the size of grains and of gradually increasing fineness. It may be observed that when

the powder of the requisite degree of fineness is nearly attained the mass should be left to settle until the following day, or, rather, until the fluid is clear; then decant carefully so as not to lose any of the deposit.

When treating a material that is soft and friable, it should be crushed between the fingers, as by using a hammer hard grains of foreign matter might be accidentally intermixed. Oil may be used for decanting diamond powder or oilstone dust for smoothing; water for rottenstone or tripoli; alcohol for hartshorn, etc.

=169.= =To prepare diamond powder.= Select rough diamonds of a blackish tint, of such a size that there are four or five to a caret. These are crushed in a hard steel mortar of the form indicated in fig. 40, the pestle being provided with a small stuffing box that can be brought down on to the mortar to prevent the escape of diamond-dust; but it is well to first crush one stone, with a single blow of the hammer on the pestle; remove all the fragments and examine the end of the pestle; it will be found that a number of particles have bedded themselves in it; these should be examined to select pieces to serve as drills and gravers. The larger fragments serve for gravers, and particles should be sought that are as nearly as possibly triangular prisms about ½■■ inch long for making drills. The other stones may be treated in similar manner till enough fragments are found. Now place all other pieces in the mortar, and continue for two or three hours striking the pestle with the hammer, turning it partly round after each few blows to prevent the powder from imbedding itself in the steel. When no “bite” is perceived in rotating the pestle, the diamond is sufficiently reduced; it is shaken out of the mortar into a watch-glass containing the most limpid oil attainable, and if necessary the fragments are released by a steel spatula, at the same time striking the external surface of the mortar with the hammer. Thoroughly mix the oil and the powder, subdividing the latter as much as possible by rubbing against the glass with a spatula; allow the mixture to rest for an hour and pour off the liquid into a second glass, leaving the larger particles behind. Leave the oil in the second glass for four hours; then decant, into a third glass with the same precautions; this is left for eight hours; the next glass sixteen hours. When all the powder has settled pour off the oil, and the several degrees are ready for use.

Some jewelers prefer to leave the powder for two or three days in a mixture of equal nitric and sulphuric acid in order to dissolve particles of steel. The acids are then much diluted with water, left for some days and decanted. Then wash the powder in two fluid ounces of pure alcohol, leave for two days, decant and dry, and afterwards treat with oil. The operation is long and hardly necessary.

SMOOTHING.

=170.= If a surface is smoothed well, the labor of polishing will be diminished by at least one-half, and it is an essential preliminary if a good gilding on brass is required.

The materials most frequently used are emery and oilstone dust for steel, pumice and water of Ayr stone for brass. The stones should not be traversed by veins, nor exhibit hard grains. Powders should be freed from large or hard grains by decantation, and it is advisable to repeat this operation several times in order to have several degrees of fineness.

SMOOTHING OF BRASS.

=171.= Every watchmaker knows that after finishing the object with a smooth file, it is smoothed, first with a blue stone or rather coarse water of Ayr stone, and then with one of finer grain. If the brass is to be gilt, the operation is concluded with a series of circular strokes, so as not to leave any striæ or bright spots; if the surface is to be _spotted_ or watered the final strokes should all be parallel.

A soft piece of charcoal applied with water may also be used on objects intended for gilding; in other cases it is used with oil.

=172.= =Wavy or watered smoothing.= This is done with water of Ayr stone and oil carefully prepared, or with a piece of wood charged with oilstone dust, etc. The oiled corner of an emery buffstick can occasionally be used.

To obtain wavy undulations on a smooth piece of metal, the finger should first be placed at the point of commencement of the undulations. Resting the wood or stone against the finger, it is moved a little in a straight line, and then in a series of semicircular waved lines, from right to left or left to right. The finger is advanced through a definite distance and the operation repeated, and so on.

A very good watered surface can be produced with soft charcoal. With a view to increasing the regularity in the marks, a rule may be laid on the object, against which the charcoal is brought.

[Illustration: _Fig. 41._]

Parallel watering is usually done mechanically, but any watchmaker can secure regularity by the following simple device.

Fix a graduated rule _t g_ across the cork (fig. 41) and two pins A A, to form stops for preventing the stick or stone from traveling too far. A division of the rule is made to correspond with the line _v v_; and, when the first line has been traced, advance the object by one, two or three graduations of _t g_, according to the interval that is to be left between successive undulations. Then trace the second wave, and so on.

=173.= =Wavy and curvilinear smoothing.= These are of two kinds; some are entire circles, which we shall proceed to consider; others radiate in curves from the circumference to some other point of the circle as, for example, many of those that are met with on keyless ratchet wheels. The latter will be discussed farther on, when discussing the smoothing of steel, for the process is identical for both steel and brass, except that with the latter named metal and nickel the stick may be replaced by a strip of zinc or tin, and coarse rouge is used.

=174.= =Circular snailing or spotting.= This is produced on a special tool by which several motions can be given to the object, but watchmakers, as a rule, so seldom have occasion to trace this class of ornament, that it will suffice to explain how it can be produced by the appliances that everyone has at hand.

The universal mandrel may be employed for the purpose, but, in that case, the operation is a very slow one, whereas, with the ordinary lathe, it can be done both rapidly and well.

[Illustration: _Fig. 42._]

Adjust a rest of the form shown at s (fig. 42), taking care that the height of the center is sufficient; the small rectangular bed _a a_ has a projecting edge, divided by equidistant graduations. To the headstock of the lathe is attached, at _b_, a piece of bluestone or wood. Having set the rest at a convenient height, and holding the object to be spotted, P, on the rest, bring in it contact with _b_ when in rotation. When the mark is made, lean the object from _b_, slide it along _a a_ so that its edge coincides with the next division and make another mark, and so on until an entire row is completed. Then raise or lower the rest and repeat the process for a second row, and so on.

Instead of applying oil to the acting face of _b_, which would have to be renewed at each operation, it is usual to cover the object P with oil, if _b_ is a stone, or with oil mixed with the substance used for smoothing, if _b_ is of wood. If this precaution is taken, the work will progress much more rapidly.

When the object operated upon is of irregular shape it must first be attached to a rectangular plate and then proceed as already stated.

A still more simple method, but one that is, in certain cases quite sufficient, consists in passing through the poppet-head a center of the form _f d_ (H, fig. 42) which is caused to rotate by the fingers or any other means.

[Illustration: _Fig. 43._]

To make spottings that, instead of being parallel, radiate from the center to the circumference, the rest _a a_ must carry a disc that can rotate on a clamping screw, and is maintained in position by a finger, with an even number of equidistant divisions on the circumference of the disc. The object to be operated upon is then fixed to the disc, and a stick used, the diameter of which is equal to the distance between two radii that pass through a pair of graduations on the disc; for example, the small circle _s_ (fig. 43). A series of circular spots is then made by gradually rotating the disc. Now replace the rod _s_ by one of the diameter _n_; advance the support until it corresponds with the position _n_, and make the second range of circular spots, and so on. The figure renders any further explanation unnecessary.

The watchmaker who has clearly followed what precedes will be able, should occasion require it, to construct a special tool acting with certainty; but it will be well to remember that there is a great advantage in driving the spotting stick by the foot, and bringing it down on the object by a small hand lever, after the manner of the drilling machines used in factories.

SMOOTHING OF STEEL.

=175.= The smoothing of a steel object is commonly done on a piece of cork, with a large iron polisher charged with oilstone dust and oil. If a flat surface, it can be finished with a copper polisher or on a sheet of glass. In the case of staffs, arbors, etc., that are not intended to be polished subsequently, a certain degree of brilliancy is given to the surface by rubbing with wood, usually pegwood, or with a stick covered with the finest emery paper and oil.

A surface that will not be subjected to friction—as, for example, the head of a screw—can be smoothed rapidly and well with a dry emery buffstick if little metal has to be removed, and the polishing can then be at once proceeded with. Only one cleaning is in this case necessary, for after the emery it will suffice to rub with pith and pass a brush over the surface.

For ordinary work, smoothing a staff or head of a screw with dry, fine emery and finishing by the friction of rather hard pith backwards and forwards, will give a fairly satisfactory surface.

=176.= =White and dead smoothing.= To produce a graining, the piece of steel must be previously smoothed in the ordinary way, perfectly flat and free from scratches. The graining is produced by rubbing the object on a sheet of ground glass with the finger, taking very small circular strokes, especially towards the end of the operation. The degree of success depends on the quality of the oilstone dust employed. It must be very fine, and it will be a prudent precaution to decant the powder in water, or preferably in oil, and not to use the earlier deposits (=168=).

When the oilstone dust is not very good, it may be washed in hydrochloric acid, which dissolves most of the hard grains, but it will require to be thoroughly washed in water afterwards, on account of the difficulty there is in removing the last traces of the acid. Of course such a method is only to be resorted to on an emergency.

Perhaps the most difficult piece to grain is a keyless barrel ratchet, because if the operation is at all prolonged the edge of the ratchet may become white before the center and it may even polish. If this happens, the ratchet should be held in the hand and rubbed with a piece of pith cut to a blunt point with a flat end. By this means it is easy to act on the center, avoiding the edges.

=177.= =Dead white or frosted surface.= After having grained the steel in the manner above indicated, if it is required to obtain a dead white frosted surface, employ a mud formed of Arkansas stone dust, or the sticky deposit on a whetstone, which is more easily obtained. It should not be too yellow, as the result is all the better according as a greater number of steel particles are mixed with the oil; at least, so we are informed by some very good workmen. A large piece of elder-pith having been divided into two equal parts lengthwise, is smoothed with a new, clean file; the mud is spread upon it, and the piece of steel is moved over it with circular strokes as in producing the graining. In this case the movement can be rapid. If the operation be well done, and if the oilstone dust used be of good quality, the object will, after being cleaned, present a beautiful uniform white surface in which the graining is still visible. Experience and knack are everything in the proper conduct of such an operation, especially in its concluding stage.

The surface may be cleaned in pure benzine mixed with a little sulphuric acid, followed by a very clean buffstick, which will impart a brilliancy to the metal.

M. Bean recommends fine Turkey oilstone powder mixed with turpentine as the best preparation for rapidly producing a dead smooth surface on steel work.

Workmen that are constantly engaged in graining employ a foot-wheel for the purpose. The ground glass is fixed so that, although not rotating, a small circular motion is communicated to it. The steel is then simply held against it; indeed, several pieces can be grained in this manner at once.

To the methods above described we would add the following, which is successfully practiced by several English workmen:

They lightly fix the ratchet, for example, by its edge, and finish the smoothing with a piece of pith, more or less charged with pure charcoal powder and fine oilstone dust. Here also knack is mainly instrumental in insuring success.

=178.= =Snailing.= To produce the snailing on a fusee or on keyless wheel-work, the device shown in fig. 44 can be used. The ratchet or fusee is mounted between one pair of centers and driven by a cord from a foot or hand-wheel. The copper or iron lap, having a diameter equal to about three times that of the surface to be snailed, is charged with fine emery powder and oil, or oilstone dust, etc., and set in contact with the face of the steel, which thus causes it also to rotate. The direction of the snailing will be the

same, whether the rotation is to the right or left. If it be required to change the direction, the relative positions of the two pieces must be reversed.

It has been already observed that brass and nickel can be snailed in the same way, employing a zinc or tin lap and coarse rouge (=173=). In some cases, hard wood laps can be used for these softer metals.

In keyless steel wheels a beautiful snailing can be obtained with Arkansas stone mud (or, in its absence, the greasy mass from an oilstone) mixed with polishing rouge.

[Illustration: _Fig. 44._]

With reference to the little tool shown in fig. 44, it may be observed that, if the axes of both the steel piece and lap were driven by bow or otherwise, the surface would be polished and not snailed.

In the absence of the tool here referred to, any one can easily construct one for the purpose which will adapt to the mandril or a foot-lathe: in order to help him in doing so we will describe one designed by M. Cadot, of Paris.

=179.= _Tool for snailing._ This is shown in fig. 45, and we would at the outset observe that it can be used equally well for polishing. To a shoulder at the extremity, A, of a piece of steel rod, B (which takes the place of the slide-rest cutter) is riveted an L-shaped piece _c c d_, and to the point _d_ is firmly fixed by a screw or rivet, the upright piece _d h_ parallel to _c c_; this piece is enlarged at _h_ so as to give a bearing to a hardened steel screw, with a hollow point, in the axis of B: the lap is supported between this screw and a hole in the center of A. The figure will suffice to indicate the form of this lap which is dished internally as shown by the dotted line. It is made of iron or copper if intended for use with hardened steel.

[Illustration: _Fig. 45._]

The piece to be snailed is fixed to a chuck of the foot-lathe, and, having fixed the rod B in place of the cutter, the lap is brought, by means of the slide-rest screws, in contact with the steel, taking care not to set it up to the center, as snailing that starts from the center is not so good. Having charged the lap with fine emery and oil, the object is rotated and it sets the lap also in motion.

It was mentioned above that this tool can be employed for polishing: for such a purpose use fine rouge, replace the lap by one of bronze or bell-metal, fix a ferrule at _i_, and, while the object turns in the lathe, rotate the lap with a bow.

By fixing a rod at L instead of at B, the tool is at once adapted to be used in an ordinary pair of turns, as it can be fixed in place of the T-rest; but it is not so easy to secure parallelism of the two surfaces.

=180.= =To restore the watered surface in nickel movements, etc.= Although the following is employed for nickel (or rather German silver) it may be well to observe that it is equally applicable to all other metals.

As these nickel movements are not gilt subsequent to being repaired, it frequently happens that the water marks on the surfaces do not correspond. By the aid of the following device watchmakers can correct this fault, but we must warn them that, as in all operations involving dexterity, they must first make experiments in order to acquire the requisite manual skill.

[Illustration: _Fig. 46._]

On a small open frame C C, fig. 46, fix several parallel bars _f l_, _e d_, etc., and on two of these adjust a slide _p o n m_, with two strips glued underneath so that it can travel up and down between _a_ and _b_. On _p o n m_, fix a guide of convenient form, as G; and, after cementing the piece, say A, that is to be watered on a board resting on the bench, place the frame C C above it and trace the figure of the guide with a pegwood stick charged with polishing material. The same figure can be reproduced in parallel rows as the guide can be moved up or down.

By varying the shape and position of the guides, the water lines can take the form of waves, festoons, circles or ovals. In the two latter cases the guide has apertures of the requisite form, and the board that carries A, not being more than half the size of the aperture, can be moved about by hand or by a tool.

If preferred, one of the bars, as _e d_, can be graduated and arrangements can be made for clamping the slide by screws in any position.

These explanations will suffice to enable any intelligent watchmaker, after a few trials, to imitate successfully any of the beautiful watered surfaces that are, on a manufacturing scale, produced by machinery.

As regards the material to be used, first mix medium rouge and putty powder in equal proportions. It will be possible to decide from the shade obtained whether more putty powder should be added, because when there is too much rouge, the surface does not acquire a good white color.

POLISHING.

=181.= =To polish brass.= When it is required that a surface be maintained perfectly flat, first dress with somewhat coarse water of Ayr with blue stone and then go over with a softer stone. Next work with fine rottenstone and oil on a felt or buffstick for objects of large dimensions and on a piece of pegwood for smaller articles. They are then soaped, washed and dried in sawdust (=151=).

The work can be accomplished more rapidly, but without maintaining a perfectly flat surface, by first employing pumice-stone and oil spread over a large piece of soft wood or felt. It is then cleaned and polished with rottenstone.

When the form permits of it, a tin disc charged with tripoli and rotating in a lathe can be employed.

Observations. Pumice-stone is powdered fine and then sifted. In using rottenstone a piece an inch or two cube is crushed between the fingers into a cup of water, and this is decanted so as to give several degrees of fineness (=168=). The polishing can best be effected by using old wood from which the sap has dried up: French chalk has but little action if the polisher with which it is applied is from the animal kingdom, horn for example, etc.

=182.= =To polish watch wheels.= Although the operation of polishing is extremely simple, it is very important that a certain degree of manual skill be acquired by practice, as otherwise the work is never of the best.

We will here enumerate several methods of procedure, in order that, after trial, each can select the method with which he finds himself most successful.

Smoothing. The smoothing should be done carefully with very soft water of Ayr stone, free from veins and hard grains and perfectly flat. The wheel must then be well cleaned.

Polishing. In polishing, rods of walnut or boxwood, of tin, bronze or zinc are used. A buffstick and burnisher are also employed.

The materials applicable are rottenstone (with oil or alcohol, being made very thin in the latter case) tripoli, prepared chalk, polishing rouge, crocus, etc. These materials have been sufficiently described in articles =165-7.= Workmen sometimes prefer to make mixtures of two or more substances, but it is more usual to employ them separately.

=183.= _First Method._ After smoothing and cleaning the wheel, it is polished while resting on a piece of cork, where it is held between the fingers which cause it to rotate; the best rottenstone is used and is applied by smooth pieces of boxwood, about 8 inches long, which are filed to a bevel edge. It is best to have the grain of the wood crosswise and the polishers should be of sufficient thickness to prevent their bending when in use.

The rottenstone can be replaced by tripoli and the boxwood by walnut. Some wheel polishers prefer a triangular stick of pure tin or zinc which is often planed to ensure perfect flatness; rouge, rottenstone or tripoli can be used with it.

The wheel, after being well washed in soap and hot water, is thoroughly dried and finished with a fine buffstick in good condition, while it rests on a cork covered with smooth felt; this operation is with a view to prepare the surface prior to using the burnisher.

Some polishers, instead of the dry buffstick, prefer one charged with a little rouge, tripoli or rottenstone moistened. But such preparations must be applied very sparingly as they involve a risk of rounding the edges.

The burnisher is next rapidly passed over the surface of the wheel, which rests on cork, covered with a linen rag, or on a piece of wood, covered with smooth paper. Some give long backward and forward strokes with the tool; others give semicircular movements. It will be found sufficient to give short strokes from half an inch to an inch in length. A slight motion of the wrist is all that is required and after a few trials the necessary skill will be attained. We cannot say more. Practice must also be relied on for determining the most suitable pressure.

The burnisher, about half an inch wide and four inches long, is curved in the direction of its length. A straight burnisher might be used, but it is less safe; the angle of the burnisher set against the pinion should be rounded off.

The burnisher is cleaned and restored by drawing across a large flat piece of walnut charged with rouge of very good quality and very pure. After being washed, a little white wax is passed over it, and then it is again rubbed vigorously with a piece of cloth or a buffstick; finally with a soft linen rag. When a tendency to stick shows itself this operation must be repeated.

=184.= _Second process._ By this method the surfaces are somewhat rounded off at the edges. But, although not so pleasing to the eye, this circumstance involves no inconvenience except that, when burnishing, the burnisher would not at once come in contact with the entire surface; we need not, however, employ the burnisher.

Laying the wheel on a cork, some workmen smooth the wheel by covering it with oil and fine tripoli and rubbing with a walnut-wood stick. Others spread a layer of such a mixture first on the stick and then rub the wheel. When no more lines are observable across the surface of the wheel it is cleaned, placed on a fresh cork that is covered with a soft linen rag, and polished with a fresh buff stick (or one that has already been used for a similar purpose) and an abundant supply of rouge or even fine rottenstone and oil may be used. The buffstick receives a semicircular movement in all directions in order not to needlessly round the corners, the edges of the teeth and the crossings.

It is then washed in warm water, bathed in alcohol and dried with a fine linen rag.

=185.= _Third process._ After smoothing with a very soft stone, rub it with a piece of the root of boxwood cut across the fibre, on which is a layer of the following composition:

Two-thirds rottenstone mixed with one-third castile soap, worked into a paste with a few drops of water so that, although not a liquid, it can be spread out at will.

Make the wheel move backwards and forwards between the fingers while resting on a smooth, good cork, without a linen rag, and, as the operation nears its completion, a semicircular motion should be given to the wood. Wash with soap, boil in alcohol and dry.

The wheel can be burnished on a cork without any linen rag and the (curved) burnisher should be moved with short circular strokes from the center towards the circumference, gradually working up towards to the extremity of the burnisher; the same portion of the burnisher should not pass twice over the wheel (see also article =166=). For common work, fairly satisfactory results may be obtained by using French chalk and a piece of hard wood.

Clock wheels are polished with a piece of felt and rottenstone. They are subsequently soaped, washed and dried in sawdust. (=151=)

=186.= =To polish lever escape-wheel teeth.= The Lancashire escape-wheel makers employ a triangular frame carrying at its corners, (1) a cutter to slit the teeth, (2) a cutter to shape them, and (3) a revolving piece of hard leather of a section corresponding to the form of the space. This latter is charged with the finest glossing stuff, used dry, and the sides of the teeth of six wheels at a time are polished by revolving the disc in each of the spaces in turn. It is hardly necessary to observe that the operation is completed before the wheels are removed from the cutting engine.

=187.= =To polish sinks or oil-cups.= A piece of pegwood, rounded at the end, is used for this purpose, rotating it in a lathe; the watch plate or cock should be inclined in varying directions to the stick in order to remove scratches. If a very high polish is required it may be given by following with a stick, the end of which is covered with wash-leather charged with rouge.

TO POLISH STEEL.

=188.= The polishing must always be preceded by a very thorough smoothing, either with oilstone dust, fine emery, or coarse rouge. If any lines are left to be erased by means of fine rouge, the operation becomes tedious and is rarely successful. The oilstone dust is applied on an iron or copper polisher. When it is desired to preserve the angles sharp, at a shoulder for example, the polisher should be of steel.

When using diamantine an iron polisher, drawn out and flattened with a hammer, answers very well.

With fine rouge, a bronze or bell-metal polisher is preferable for shoulders; and, for flat surfaces, discs or large zinc or tin polishers, although glass is preferable to either of these.

After each operation with oilstone dust, coarse rouge, etc., the polisher, cork, etc., must be changed, and the object should be well cleaned—preferably by soaping; perfect cleanliness is essential to success.

Fine rouge or diamantine should be made into a thick paste with oil; a little is then taken on the polisher or glass and worked until quite dry. As the object is thus not smeared over, a black polish is more readily obtained, and the process gets on better if the surface is cleaned from time to time.

=189.= =To get a good black polish.= As just pointed out, this is mainly secured by using very little polishing material at once, in a very little liquid on either, the polisher or glass plate and drying up quickly. If the surface does not prove satisfactory at first, it will often be found that a final rapid and light application of dry diamantine or rouge on a piece of glass or pith will produce a brilliant black polish.

If operating on an axis or staff, polish as well as possible, first erasing the marks of the graver or file, and then, hold the ferrule between the fingers, rotate it with one hand and with the other rub the axis lengthwise with a pegwood stick charged with rouge or diamantine.

A rod will show a black polish if it be rubbed lengthwise with emery paper of gradually increasing fineness, oil being applied with the finest quality.

To polish flat surfaces. Place the object on a sound piece of cork covered with a clean rag and rub with, a long strip of ground glass.

To polish a square shoulder. Fix a rod in place of the T-rest of the turns, and set it in such a position that the polisher rests on this vertical rod when lying flat against the shoulder. Another and better method consists in cementing or otherwise fixing in the plane of the shoulder a brass disc of such dimensions that the polisher is constrained to remain flat.

Observations. The corner of the polisher that is used for polishing a shoulder should be neither right-angled nor too acute. In the first case it would round off the shoulder, and in the second it would become soon distorted and leave dull radial marks on the surface.

Diamantine should not be used for polishing the acting surfaces of pivots, the pallets of escapements, etc., since this material, as well as emery, is liable to leave particles embedded in the steel which occasion rapid wear.

CEMENT, WAX, RESIN, ETC.

=190.= The principal uses to which the watchmaker applies cement is for fixing objects in the lathe, pallet-stones in position, as well as locking and unlocking pallets, ruby-pins, etc.

The selection of a cement or wax is not a matter of indifference; fine sealing-wax causes objects to adhere firmly together, but many of the best workmen prefer refined shellac. Certain kinds of wax are too dry, the consequence being that a false stroke of the graver will often detach the piece; others are thick and soft, and are apt to heat rapidly under the action of the burnisher or polisher, so that the object is displaced. It is only by making a series of trials that the efficiency of the material can be ascertained. Some workers claim that a mixture of sealing-wax and shellac gives good results.

=191.= =Mode of applying cements.= When employing wax, resin, cement, etc., for uniting two objects, it is important to note that the mode in which it is applied has an important influence on its efficiency. The following observations on this point are due to M. Sibon, and the reader will be able to select those portions that have reference to his work.

When two objects are united by a cement, this will lose much of its value if unskillfully applied, and, in order to use it to the best advantage, the following practical rules should be observed.

1. The surfaces to be united must be quite clean.

2. The less cement, wax, etc., that is interposed between them, the better they will adhere. This is owing to the fact that with a thick layer the object has, at the junction, no more rigidity than that of the cement itself; as a rule this more fragile than the material it is

employed to unite.

3. There should be perfect contact between the cement and the surfaces. With a view to securing this, the object must be first heated to a point such that the wax or cement cannot solidify without having first had time to effect a perfect union.

This remark is especially applicable when using sealing-wax, mixtures of resin, shellac, and similar materials. They will not adhere firmly unless the surfaces have been heated very nearly to the point of fusion of the cement. The sealing of letters offers an example in proof of this assertion. When the seal has been used several times in succession or been left too long on the wax so as to become hot, it will adhere and cause some inconvenience if further employed.

With hot melted glue, adhesion is best secured by friction or a moderate pressure.

Sealing-wax is excellent for uniting metal to glass or stone, providing they are sufficiently heated to melt it; for, if applied to cool surfaces, it will not adhere at all. By heating two pieces of glass or stoneware sufficiently to melt shellac, a small quantity will suffice to make them adhere firmly together; notwithstanding that every one has seen such joints, very few succeed in making them, for the simple reason that they do not recognize the necessity of heating a delicate piece of glass or china to the point which is essential for securing a good result.

In conclusion, the principal obstacles to adhesion are air and dirt. The first is always present; the second is due to accident or carelessness. All surfaces are covered with a thin layer of air that is very difficult to remove; its influence prevents highly polished metal from being moistened when immersed in water. So long as this layer of air is not displaced, the cement cannot adhere to the surface to which it is applied, because it cannot come into direct contact. The most effective agent for displacing this air is heat. Metals heated to about 75° C. (170° F.) are immediately moistened on being plunged into water, hence it follows that, as regards cements that are applied in a fused state, heat is the best means of bringing them into intimate contact with the surface.

We would add that, in addition to possessing this advantage, the application of heat also renders the surfaces more penetrable to the layer of cement, after the manner of soldering, and makes the interlocking of the molecules more perfect; this explains the greater degree of tenacity of a well made joint with only a thin layer of cement.

=192.= =To set in wax in the lathe.= Trace a series of concentric circles on the face of the chuck with a graver point, after turning it true: this will increase the adhesion of the cement. Then the flame of the spirit lamp is held under the rotating chuck and, when this is hot enough, its surface is covered with a layer of shellac or sealing-wax, and the object is held against it. Holding it in position with a piece of pegwood supported on the T-rest, the lamp is removed and the lathe kept rotating until the cement sets. The cooling can be hastened by applying a small moist sponge, but it should not set too suddenly.

If the object requires to be very exactly centered, its position must be insured while the cement is still soft by means of a long pegwood stick in its central hole. This stick is held in position until the cement sets, steadying it between two fingers close up to the chuck. The slightest eccentricity will be indicated by a motion of the free end of the stick.

If the object is round, and has no central hole, it must be centered by its circumference, holding the pegwood in front, or resting against a corner of a circular elevation or depression, as, for example, the collet of a wheel, or of a cylinder riveted to its balance, etc.

The beginner should make a number of trials; they will enable him both to acquire lightness of touch, and to recognize the proper degree of softness of the cement for centering, as well as its tenacity.

When it is essential that the two faces of the object be strictly parallel, a precaution is necessary; this consists in leaving on the face of the chuck a slightly projecting circular rim with a fine smooth edge, and of a diameter rather less than that of the object. By moving this latter backwards and forwards after applying it to the wax, and pressing it into close contact while cooling, the requisite parallelism will be secured.

=193.= =To fix a pallet-stone, etc., in position.= To fix a pallet-stone or an end-stone by means of shellac it is usual to place a small piece of the latter round the stone when in position and apply heat. But very often the lac spreads unevenly or swells up; and this, in addition to being unsightly, is apt to displace the stone. The inconvenience can be avoided as follows: The pallets are held in long sliding tongs, and, taking a piece of shellac, heat it and roll it into a cylinder between the fingers; again heat the extremity and draw it out into a fine thread. This thread will break off, leaving a point at the end of the lac. Now heat the tongs at a little distance from

the pallets, testing the degree of heat by touching the tongs with the shellac. When it melts easily, lightly touch the two sides of the notch with it; a very thin layer can thus be spread over them, and the pallet-stone can then be placed in position and held until cold enough. The tongs will not lose the heat suddenly, so that the stone can easily be raised or lowered as required. The projecting particles of cement can be removed by a brass wire, filed to an angle and forming a scraper.

To fix an end-stone, the cap must be held by its edge in the sliding tongs, and shellac carefully applied around the edge of the hollow. It is advisable to hold the cap in a small tool formed of two parallel blades, as when reversed so as to press the stone on a flat surface, the shellac will spread over the end-stone, from which it will be removed with difficulty.

ENAMEL.

=194.= This name is applied to an opaque glass, with which various metallic compounds, such as oxide of tin, phosphate of lime, borax, etc., have been incorporated by fusion. The color, of course, varies with the substance so added.

Willis recommends the following as a good white enamel for dials: silver sand, 14 parts; borax, 10 parts; red lead, 18 parts; niter, 2 parts; oxide of tin, 12 parts; flint glass, four parts; and binoxide of manganese, 1-50th of a part. But a good deal of care is requisite, both in selecting the materials and preparing the enamel, in order to insure a pure color of any desired shade; it is, therefore, often desirable to purchase the enamel ready prepared.

In applying enamel, regard must be had to the relative dilatation of the metal to which it is applied, the two being so combined as to expand and contract together; otherwise there is danger of the enamel cracking, either at once or shortly after it has set.

Enamel may be applied to gold or copper. Associated with the latter, it forms the ordinary dials of watches and timepieces, and, with the former, it serves for making enameled gold dials or cases. The gold should be of 22 carat, the 2 carats of alloy consisting of equal parts of silver and copper. If the gold is of a higher standard, it will not adhere so well, and, if lower, there will be a further danger of melting the metal before the enamel is fused.

Silver is apt to cockle on the application of heat, and enamel applied to it presents a bubbly appearance.

=195.= =Application of enamel in the cold.= We are indebted for the following particulars to M. Fournier, of Dieppe, a well-known enamel maker:

There are two kinds of false enamel for application, when cold, to damaged dials.

The first, a mixture of white resin and white lead, melts like sealing-wax, which it closely resembles. It is advisable, when about to apply it, to gently heat the dial and the blade of a knife, and, with this, to cut a piece of enamel of the requisite size and lay it on the dial. The new enamel must project somewhat above the old. When cold, the surface is levelled by scraping, and a shining surface is at once produced by holding at a little distance from the flame of a spirit lamp. It is necessary to be very careful in conducting this operation, as the least excess of heat will burn the enamel and turn it yellow; it is, however, preferable to the following, although more difficult to apply, as it is harder and does not become dirty so soon.

The second false enamel contains white lead mixed with melted white wax. It is applied like a cement, neatly filling up the space, and afterwards rubbing with tissue paper to produce a shining surface; if rubbed with a knife blade or other steel implement its surface will be discolored.

PRECIOUS STONES.

=196.= The principal precious stones used in watches, chronometers and regulator clocks, in their order of hardness, are: diamond, ruby, sapphire, chrysolite.

A watchmaker, although he may not have had any previous experience of jewels, can easily ascertain their relative hardness by rubbing one against the other. The softer will be scratched by those that are harder, and the stone that can be marked by a file may be thrown aside as useless.

=197.= =Diamond.= We shall make a very brief reference to this stone, as it is not used except for the end-stones for balances for chronometers and high-class watches.

Splinters of diamond are employed for drilling materials of a less degree of hardness, and fragments fixed at the end of a rod are used for turning very hard steel; diamond dust is the principal material used for working precious stones, polishing, etc. (see articles =165= and =169=).

=198.= =Ruby.= This jewel, of a rich, velvetty, red color, exists in three principal varieties: oriental, spinel and balas rubies, which differ as regards their chemical composition.

From a jeweler's point of view, the value of a ruby is enhanced by its rich color and transparency; but this is not the case in regard to its application in horology, for which hardness and capability of taking a high polish are mainly necessary.

The specific gravity of the three varieties is: oriental, 4.2; spinel, 3.7; balas, 3.6.

The first of these is the best, since it is the hardest, both taking a better polish in the first instance and retaining it for a longer period.

In comparison with the other varieties, its specific gravity is greater and it possesses a brighter color, but will often be found to be less transparent.

Spinel and balas rubies are frequently met with that are very beautiful to the eye, but their hardness is inferior to that of the sapphire and even of the chrysolite. They must be carefully excluded from all good work, for, either in consequence of the inferior hardness or the mode in which the oxide of iron, magnesia, etc., is combined, or of other causes, oil rapidly deteriorates in contact with them, and the moving parts, especially if they are of steel, soon show signs of wear. The rubies themselves also suffer, and it is by no means uncommon, especially in the case of the duplex escapement, to meet with such jewels quite rough and even pitted on their acting surfaces.

=199.= _False ruby._ In a certain class of watches, a variety of stones pass for rubies that are known to jewelers as rubicelle, rubace, rock ruby, Brazil, Siberian or Bohemian ruby, rose ruby, etc., the hardness of which is even less than that of rock crystal. Pivot-holes made of these imitations of the real ruby are worth less than plain brass settings.

=200.= =Sapphire.= The color of this stone, sometimes even milky, passes through all the shades of blue. Like the ruby, there are several varieties that differ appreciably in regard to hardness. The hardness of oriental sapphire is equal to that of oriental ruby; both consist of nearly pure alumina, colored by a little oxide of iron; their chemical composition thus being the same, they only differ in regard to color. It is, then, a great mistake on the part of watchmakers to prefer spinel or balas rubies in place of oriental sapphires.

The sapphire is more brittle than the ruby.

The other kinds of sapphire, such as water sapphires, are not true sapphires; they are soft and should never be used in horology. The density of the oriental sapphire is about 4.01, whereas that of other kinds is only 2.58.

=201.= =Chrysolite.= Under this name lapidaries include a variety of stones of yellow-green, apple-green with shades of yellow, and other colors.

That known as oriental chrysolite, which is the same as the oriental topaz, has a beautiful pale yellow color with shades of apple-green; it is the most highly esteemed. This stone has a sufficiently high degree of hardness for use in watchmaking, as it will scratch rock crystal. Its density varies from 3.73 to 3.00.

The other varieties, ordinary chrysolites, come very low in the scale of hardness. They can be scratched by quartz, rock crystal and even by the file, and are thus of no use for watches.

=202.= =Agate, Carnelian, Topaz.= Only the varieties of the stones already considered that are termed oriental can be used for the pivot-holes or the pallets of astronomical regulators, but for the escapements of the ordinary timepieces of commerce, such, for example, as the pallets of Brocot escapements, the topaz, agate or carnelian may be used. When of the hardest kind, and capable of receiving a high polish, they will very efficiently resist the friction of brass teeth. As to the softer kinds, they are inferior to hardened polished steel for pallets.

WORKING IN PRECIOUS STONES.

=203.= The methods adopted for working in the precious stones are in great parts kept secret by those who practise them; it is, however, well known to watchmakers that jewels are usually worked and polished with powdered diamond, and the following details will afford all the information necessary to enable the reader to make a jewel of any required form. Where not otherwise stated, the information is taken from a work published by N. Dumontier.[5]

=204.= =Tools for working jewels.= These are all of simple construction, and can be made by any watchmaker if, indeed, he has not them already to hand.

[Illustration: _Fig. 47._]

(1.) A small lathe arranged to receive chucks, fixed to the bench or in a vise, and driven by a foot-wheel. Its form resembles that shown in fig. 47.

(2.) Two circular laps of copper and one of tin about 2 inches in diameter and ■th inch thick; these present a flat face for grinding, smoothing and polishing the stones, and are adapted to the nose of the lathe.

(3.) A small barrel (that also screws into the nose of the lathe) with six brass covers, perforated at the center, on which to cement the jewel-holes, when enlarging, smoothing and polishing their holes.

(4.) A flat steel circular cutter half an inch in diameter, for slitting stones. Also two similar discs, one of copper and the other of tin, of the same size, and having sharp edges, are occasionally useful.

(5.) Two small laps, one of copper and one of tin, to smooth and polish cylindrical stones. These laps are mounted in place of the T-rest, or in the slide-rest, in such a manner that they can be rotated in a horizontal plane by a bow, in a manner sufficiently indicated by fig. 48.

[Illustration: _Fig. 48._]

(6.) Two chucks adapted to the lathe, on which to cement the jewels for drilling, turning and polishing.

(7.) A number of small broaches, spindles with concave and convex ends, etc., for smoothing and polishing jewel-holes, convex and concave surfaces.

There may also be added a small steel plug mortar for powdering the diamond (=169=), and a flat steel plate with a block for working up the powder.

=205.= =Selection of Stones.= This is of the first importance. By the aid of a powerful lens, or a microscope, ascertain that they contain no cracks, air cavities or black specks; avoid stones that are milky, preferring such as are marbled, and in which the directions of crystalization seem to cross one another, as they are the hardest. The hardness may be tested by trying them one against the other (=122=), but an experienced workman needs only to note the amount of resistance it offers to the operation of cutting on the lap. The density also affords a valuable means of determining the nature of stones. (See above notes on the several kinds.)

=206.= =To find the axis of crystallization of a stone.= It is well known that jewels differ from glass, in that they form crystals of certain definite forms; they are therefore termed “crystalline,” whereas glass is “vitreous.” If a jewel-hole is drilled in any direction other than the axis round which the crystal may be assumed to have been formed, there will be difficulty experienced in the drilling and polishing; the edges of the hole will become rough during the act of rounding them off, and the hardness will appear to be irregular. This point seems, however, to be ignored by the majority of jewel-hole makers, although the determination of the most suitable direction presents no difficulty.

Obtain, from any optician, two tourmaline plates cut parallel to their axis of crystallization and with their faces polished. Mount them in a light frame, parallel to each other, so that each can rotate independently of the other round the axis through their centers; it is convenient if a light spring tends to bring the plates together so that a stone can be held when placed between them. Or such an arrangement can be bought ready made at most opticians: it is known as a tourmaline polariscope. If this instrument be held up between the eye and a light, and one plate be rotated while the other remains stationary, it will be seen that the light becomes gradually greater or less according to the direction of rotation; and further, if the plates be good ones, a point will exist at which there is nearly total darkness.

To examine a stone, cut and polish on it two parallel faces approximately at right angles to the axis of crystallization; this can generally be roughly guessed at by inspection. Place it between the plates (when set at their darkest position), and not only will the light be in part restored but beautiful colored rings will be formed. If they are circular, the faces of the stone are at right angles to its axis; if not, incline it till the rings become so, and the axis will then coincide with that of the instrument. In case the rings are not observed at all, the stone must again be cut at right angles to the original direction, and the experiment repeated. If they still do not appear, the stone is unsuitable for drilling, but may be used for pallets, locking-stones, ruby-pins, etc.

The stones to be examined in this manner must be larger than those commonly met with, and if cylindrical rubies can be obtained they are to be preferred, as it is then only necessary to slice them across their axis.

It should perhaps be observed that these precautions can only be taken in making jewel-holes for the higher class of clocks, chronometers and watches. The cheaper class must of necessity be cut in such a manner as their figure may suggest.

=207.= =Making jewel-holes.= Having selected 20 or 30 stones of about the same height, cement them to a smooth brass or copper-plate, heated to melt the cement. Hold this plate in contact with a revolving copper lap in which the coarser quality of diamond powder (=169=) has been embedded by means of a hard steel block; the lap is moistened with water.

When one side of the stones is true, soften the cement and, after washing, place them in a vessel containing spirits of wine heated by a lamp. After doing the same to the plate, again cement the stones to it with the trued sides downwards, and grind the other faces until the desired thickness is arrived at. Clean the stones and smooth them on the brass lap charged in a similar manner with a finer quality of powder.

The stones are now ready for drilling. This may be done with diamond powder, or with the diamond drill, both of which methods will be explained.

=208.= _To drill with powder._ In drilling with powder, the stone is fixed with sealing-wax or shellac on a carrier that is adapted to the tool-holder of the slide-rest, this carrier being provided with a vertical slide, so that by the screws in three directions the stone can be accurately centered; it is, moreover, so arranged that the stone can be advanced to or from the drill by pressing with the finger axially. Drill a small hole in the center of the chuck and, after fixing a piece of steel in it that has been hardened and tempered to a greyish color, turn a point on it about twice the length of a pivot, to serve as a drill. This point must be slightly thinned backwards to prevent it from choking in the hole and its end should be flat, so as to retain the powder.

When the stone is exactly centered, place No. 2 diamond powder on the end of the drill, and press the stone gently against it, constantly releasing it from the drill for an instant at a time. The hole will be perforated in from 8 to 15 minutes, according to its depth, during which interval the powder should be renewed two or three times. Remove the stone and fix it on the barrel-chuck cover so as to turn true in the lathe; then turn out the oil-cup with a diamond graver of suitable form. See again that the stone is central, and re-center it if this be found necessary. This is done with the smooth conical end of a soft round broach, or a pegwood, a lamp being held under the chuck at the same time.

=209.= _To use the diamond drill._ Having centered the stone on the chuck, as explained in the preceding paragraph, set it in rotation and bring a sharp-pointed diamond graver against its center, pressing lightly and resting the handle on the =T=-rest; a minute central mark is thus made in the stone for maintaining the drill axial. Selecting a diamond drill of convenient diameter, moisten it in the mouth and present it to the mark, applying a gentle pressure, the amount of which can only be ascertained by practice. It is to be observed that a number of stones should, if possible, be drilled at the same time, for the hand is apt to lose the requisite knack, if only one or two are perforated at a time.

=210.= =Smoothing and Polishing.= When the hole is made through, remove the stone and invert it on the chuck. The diameter being less than that ultimately required, pass a brass broach charged with No. 3 powder through the hole, giving it a gentle axial motion while the stone revolves, and taking care to avoid pushing it so far forward as to lock in the stone, and holding it very lightly between finger and thumb. When sufficiently smooth, clean with rotten wood or soft bread, and treat it in a similar manner with a copper broach and No. 4 powder. Then again clean and use a tin broach and powder No. 5. Next, taking a small bone cone, smooth the angles of the holes; then use a copper wire with rounded end for smoothing the oil-cup (with powder No. 3); follow as explained for the hole with the finer degrees. Using a finely pointed pegwood that passes through the hole, _marry_ or round off the internal angle between the hole and oil-cup (the powder that remains in the hole being sufficient for this purpose) and do the same

to the outer circumference of the cup with a copper spindle of somewhat larger diameter.

Round off external angles with a diamond graver followed by a copper polisher, the end of which is cup-shaped. The flat face of the stone is polished with a small copper disc and No. 4 powder, pressing it lightly with the finger at the same time that a circular movement is given to it; finish with No. 5 powder. Or the stone may be detached and the flat face polished by working on a ground glass plate, a pegwood point being passed into the hole to form a handle.

Re-set the stone, inverting it, on the chuck, centering it. The other side is then polished in the same manner, using such tools as its form may require.

Having thus completed the stone, examine it carefully with a powerful glass to ascertain that the hole is highly polished and the angles rounded off, etc. It is then ready for setting.

=211.= =Setting Jewel-holes.= Whether it be a plate, cock or bushing in which the stone is to be set, the piece must always be cemented to a chuck and the hole accurately centered. Turn it out to a depth corresponding to the thickness of stone, and make a circular groove round the hole thus made with a round-pointed graver, only leaving a very thin fillet of metal on the inside. The stone should fit easily in the hole, but without play, and should pass in to such a depth that its surface is slightly below that of the plate, etc., when there is an end-stone; in other cases it must, of course, often depend on the end-shake to be obtained. At the same time it appears desirable that it always should be slightly below.

Clean out the setting and place a small quantity of oil in it to prevent the stone from flying out when made to rotate; or it may be rendered still more safe by a pointed pegwood held in the hand. The stone is fixed in position with a small conical burnisher (as, for example, the point of a round broach) very carefully polished, so as to avoid all abrading action; if an excess of metal is forced over the surface of the stone, it is removed with a graver. The surface of the brass is finally smoothed with pith or pegwood, and tripoli in oil, followed with polishing rouge in spirits of wine.

English jewel-setters often do not turn the groove, but leave a projecting edge round the hole, which is pressed on to the stone with a burnisher.

=212.= =To Make End-stones.= The details already given will enable any intelligent workman to make end-stones. If one of diamond in a brass or steel setting is required, take a small rose-cut stone, turn out a hole in the chuck to receive it, and, after cementing in position, turn off the corners with a diamond graver so as to be able to set it.

For making end-stones of ruby, sapphire or chrysolite, flatten a face, using the laps Nos. 1, 2, and 3 in succession, or a plate of ground glass. Then cement with the flat face towards the chuck, and turn to the requisite form with a diamond graver. Polish with the cup-ended brass and copper spindles, and set, if requisite, in the same manner as a jewel-hole.

=213.= =To make pallets, unlocking pallets, etc.= This may be done on the lap, or by using files of soft steel, copper and tin. In the first case the stones are roughed out while held by the hand, and the required form is given them while holding them in a small carrier that fits into the T-rest support, but the forms of such stones are so various that no special details can be here given. The diamond powder of different degrees of fineness is used, as in making jewel-holes.

=214.= =To make semi-cylindrical locking stones, ruby-pins, etc.= The stone must first be made approximately cylindrical on the lap No. 1, so that it may be turned with the diamond graver. Drill a hole in the chuck, cement the stone in it and turn it in this manner. When true and of the requisite length and diameter, round off the outer end and smooth with a cup-ended spindle, then polish with powders 3 and 4 successively. Round off the sharp corner with a cup of rather greater curvature. The cylindrical surface is polished by means of a small lap carried on a vertical spindle in a frame fixed in the T-rest support, and caused to rotate rapidly with a bow, the lathe-head also revolving at the same time (=179=). The lap-carriage should have a vertical screw adjustment so that it may be brought just into contact with the stone; it is supplied with the several degrees of powder in turn. Now drill a hole in another chuck of the diameter of this cylinder, fix it in position and finish off the opposite end.

To form the flat face along the axis of the stone it is cemented to a support in place of the =T=-rest and brought against the revolving lap in the lathe; or the same result may be attained by using a brass file.

=215.= =To make a duplex roller.= At the present day this operation so rarely has to be done that only a few words can be devoted to its consideration.

Very pure rubies must be selected, and the hole drilled as explained in =209=; if the drill is too short it must be introduced at opposite ends, and the two holes made to meet. After smoothing the surface, the notch is cut with the thin steel cutter referred to in article =204=, the roller being cemented to a support that replaces the T-rest. When the steel disc charged with powder No. 4 is revolving very rapidly, advance the roller under it by a screw. The notch is polished by a small copper file of suitable form, and its corners rounded off by a tin one of square section, one edge of which enters the notch.

=216.= =To mount diamond drills and gravers.= Drill a hole or file a notch in the end of a piece of brass wire to correspond with the fragment of diamond; heat the end in a spirit lamp and lay on it a piece of good sealing-wax or shellac. When this commences to melt, set the diamond in position and leave the whole to cool. Diamond drills are very commonly mounted at the end of a pin that has had its point filed off; mark a point on the end with a graver and drill the hole, which should be very shallow. Holding the pin in a pin-vise with its point projecting about 1-10th inch, heat the vise in a lamp, and proceed as above explained.

FOOTNOTES:

[4] The theoretical density of an alloy, on the assumption that in alloying the metals do not contract or expand, is obtained by dividing the percentage proportion of each constituent metal by its density, adding the products so obtained together, and dividing their sum into 100.

PART III.

HEALTH AND MANIPULATION.

PRESERVATION OF HEALTH.

=217.= Some of the following directions may perhaps be considered to be over-minute and too restrictive; but they are not so. Good habits contracted in youth are easily maintained, and, when the watchmaker has tried them long enough to convince him of their influence on his health, he will experience no difficulty in keeping them up.

THE SIGHT.

=218.= When working at any small mechanism, such as a watch, it is necessary to use the glass, but this practice is apt to produce inflammation of the conjunctiva or cornea and a weakening of the eyesight; a too frequent and prolonged use of the glass will have the same effect as using spectacles that are too strong.

In order to preserve his eyesight, the watchmaker should take the following precautions:

He should not retain the glass at his eye by a contraction of the muscles for more than a brief interval of time. The glass holder, which can be at once set in any desired position, has therefore much to recommend it.

Drill a few holes in the frame of the glass to avoid or at least diminish the inconvenience that arises from the heating of the enclosed air, as well as from the deposition of moisture on the surface of the glass.

Do not use glasses of too great magnifying power; they needlessly fatigue the eye.

Only use glasses that are truly achromatic. If compelled to use the ordinary simple glass, place a ring of dead black paper inside the frame and against the lens, which, by diminishing the field of view, will reduce the inconvenience due to spherical aberration.

It is hardly necessary to advocate the use of a green cardboard shade to the lamp, as they are so generally used by watchmakers. It should be so arranged as to protect the head and eyes from radiation, and cardboard is preferable to metal as it radiates less heat.

Working at night and by artificial light, more especially by the dazzling light of gas, fatigues the eyes much more than with ordinary daylight, and the workman will find it a relief, if obliged to work by artificial light on very minute objects, to rest his eyes frequently on large stationary bodies. If he can do so, it is a great comfort to bathe the eyes in cold water.

It is good practice to habituate oneself to the use of either eye with the glass.

By adopting these simple precautions, how many of our fellow-workers who are now only able to see objects indistinctly and suffer from incipient blindness would have preserved their sight uninjured. And there is yet another precaution that has been pointed out by Dr. Haltenhoff, of Geneva. He has shown that by avoiding an excessive indulgence in alcoholic drinks or tobacco, many old watchmakers in that town have succeeded in preserving their sight unimpaired, and it is impossible to doubt the truth or over-estimate the importance of this fact.

The same authority draws attention to the necessity of taking care that, before adopting watchmaking as a trade, youths should ascertain that they do not suffer from progressive nearsightedness, which is often hereditary, as in such a case they would most certainly be compelled to abandon it in after life. Boys should not be set to work on such small objects as the details of a watch too early in life, before the membranes of the eye have assumed a certain degree of rigidity.

Mr. Brudenell Carter, a well-known ophthalmist, is of opinion that the habitual use of the glass by watchmakers has the effect of actually developing and preserving the power of the eye.

THE BODY IN GENERAL.

=219.= It is often found that an old, or even middle-aged watchmaker is irritable, often tired and soured. This arises, not so often from an over-excited uneasiness in regard to his trade, an explanation that is usually urged, as from a derangement of his digestive organs brought about by the habit of life he is compelled to adopt. Prolonged working at minute horological mechanism is perhaps more wearying to the mind and body than any other trade or occupation.

To avoid its ill effects the watchmaker should adopt the following precautions as far as possible:

Do not use a stool with a stuffed seat, but prefer one of cane or wood.

Take care that the relative heights of the board and stool are such that an excessive compression of the muscles of the chest, etc., is avoided during any long operation that renders it necessary to maintain the body in a constrained position.

A stool with adjusting screw similar to a music stool is convenient from this point of view.

Change the position as much and as often as possible, especially when working with the file or graver. With this object in view many workmen have a second board of such a height that they can work standing.

When using the lamp let it always be provided with a cardboard shade as already recommended.

A screen to protect the head from the direct heat of the flame is often found advantageous; in fact, the watchmaker should adopt the advice of Boerhaave: “Keep the head cool and the feet warm.”

Let him always remember that nothing does more harm than sitting to the bench immediately after a meal. He should allow an interval of half an hour to elapse and with some temperaments, even this is not enough; during this period he should only do work at which it is possible to stand. A little exercise, such as a walk that is not hurried, will be still better; it will stimulate the circulation and stretch the muscles that have been maintained in a constrained position for a long time through the prolonged attention and slight motion that his labors involve.

USE OF THE FILE AND GRAVER.

=220.= The first operations that a watchmaker ought to learn are to file flat and square, to turn round, to forge, to hammer-harden a piece of metal without deteriorating it. These accomplishments are but too much neglected in the modern training of an apprentice, an omission that is partly owing to the want of good instructors and partly to the shortness of the time he can afford to devote to learning his trade.

TO FILE FLAT AND SQUARE WITH BOTH HANDS AT ONCE.

=221.= It is a very common practice to place an old file in the hands of an apprentice, to fix in the jaws of a vise a piece of metal, either brass, iron or steel, and to set him to work rubbing and filing the surfaces with great labor, the only result being that they are utterly mis-shapen and covered with brilliant spots.

This method is bad. The action of the file is mechanical and the problem that has to be solved is the following: To produce good work in the shortest possible time, and with the least expenditure of force. It is therefore only by very slow degrees that an apprentice can hope to acquire the requisite ability, if he is set to work trying to shape an object in some hard metal before he knows how to maintain lines straight and surfaces flat. Not knowing how to proportion his effort to the resistance to be overcome, and allowing the file to travel irregularly over the surface, he gets confirmed in the tendency to give a rocking motion to the file, whereby the surface is left round, and he will find it all the more difficult to throw this habit aside.

It is far better to let him commence on round pieces of common wood, filing with a rasp or coarse-cut file, without removing too much at once. By this means he may rely on learning to file flat and square by the eye alone without the aid of a straight-edge.

When he works well in common wood, he can be set to file harder woods, box for an example, roughing with a rasp and finishing with a new bastard file. He should not be allowed to have hard wood until able to file a surface so well that, on placing a metal rule across it in any direction, it is found to be flat.

=222.= Let him then advance to brass, which, if cast, should be previously dipped in acid to remove the hard surface, as this should not be filed off. The resistance it offers would cause a jerky motion of the file that would be apt to disturb the slight amount of decision the hand has already acquired.

As brass opposes a considerable resistance, the pupil should be carefully watched with a view to preventing too rapid movement and an excessive pressure, involving waste of power, while he fancies the work is being proportionately advanced; the manner in which the file is applied to the surface should also be observed, taking care that little or no pressure is applied during the backward stroke. The teacher should both explain and demonstrate that the main secret of success consists in a perfect equilibrium between the actions of the two hands; one should increase as the other decreases with the horizontal motion of the file, since the two levers in use, namely the portions on either side of the point of contact, are continually the one increasing and the other decreasing.

By filing steadily and attentively, the hands will gradually acquire the requisite sensitiveness, or tact, that enables each to adjust the pressure in proportion to the other, as well as the knack that enables them to maintain the surface flat. It is important to avoid short and jerky movements.

Practical instruction from a competent teacher must be relied on to complete the directions here given; no written instructions can replace it.

It is advisable to use new, or nearly new files in the above lessons; the wear will have brought them into good condition for working iron or steel.

Proceed with these metals as already explained in regard to brass, and special attention must still be given in order to prevent hurry on the part of the pupil. The files remove less metal at a time and a greater pressure is necessary, so that he does not make such rapid progress as with brass, and this gives rise to a tendency either to use new files, which are soon spoilt, or to give the stroke too suddenly, while applying considerable pressure, especially during the return stroke. He thus heats his file, breaks off the crests of the teeth, which become embedded in the metal and do much to further damage the file. Moreover, he will lose some of the sensitiveness of touch that his hand has already acquired.

=223.= It would perhaps be well to subdivide the day into three parts for as long as appears necessary; the first to be devoted to filing, the second to turning, and the third to forging and cold hammering.

By this means he will be quicker in acquiring the requisite skill of hand and eye, and, when he has attained to this ability, it will be time to practice himself in the management of various tools. Feeling certain of himself he will soon become quick in his work.

It is prejudicial to the true instruction of a pupil and a false economy of both time and money, to let him commence either a clock or watch before arriving at this point. He will experience difficulty in making even the simplest pieces, which, besides being very badly made, will take up a long time; he will keep forgetting as he goes on, because, owing to the slowness with which he works, the construction of a machine occupies months, or even years, whereas it would only have occupied a few weeks, or months, if he had possessed sufficient manual skill to enable him to handle properly the file and graver.

We insist specially on the need of this preliminary training of the young horologist, because, with very rare exceptions, if a pupil is set to delicate details before he is master of his tools, he works with a want of decision, and, therefore, with difficulty. He will, as a

rule, make a workman of but moderate ability, and will soon become disgusted with his trade, from the mere fact that he cannot work with ease and rapidity.

Time is an element of success; hence gratuitous apprenticeships for short terms, that become a tax on the master if he does not soon make use of his pupil's services, will very seldom produce good watchmakers.

TO FILE FLAT WITH ONE HAND.

=224.= When an object is to be held on a cork or wood block fixed in the vise, with one hand, and filed with the other hand, special care must be taken to lay the file flat without any hesitation after each return stroke, and the hand should be able to feel if the file is wrong in this respect, and to at once bring it flat. After the pupil has learned this, he will very soon be able to adjust the pressure and the force exerted in moving the file horizontally, so that it shall remove an equal amount from the entire surface operated upon. It often happens that the object can conveniently be rested upon a finger of the left-hand while the right-hand holds the file. The maintenance of the file flat is in that case much easier.

=225.= _Mechanical device for filing flat._ This (the _pradel_) consists in placing behind the workman a horizontal bar, on which rests one end of the file handle, prolonged for the purpose to about a yard in length; thus the file has two points of support: the bar, adjusted at a convenient height, behind the workman, and the object to be filed flat fixed in the vise in front.

This method, while convenient for amateurs, may be utilized in teaching an apprentice, letting the supports be hinged at one and press at the other end on a rather strong spring index, which must be prolonged so as to be brought under the eye of the pupil.

The displacement of the index will show him every false movement of his hands, and will guide him in adjusting them. It would be best if the prolongation of the handle were as light as possible, but rigid and arranged so that the file can be held naturally.

TO TURN CYLINDRICAL PIVOTS, ETC., AND SQUARE SHOULDERS.

=226.= Just as in working with the file, advice and demonstration by a good master are here indispensable.

The materials should be worked in the same order as is explained in parts =221-4=; that is: wood, brass, iron, steel, hardened and tempered steel; no one sample being set aside until the student can turn it perfectly round, flat on shoulders, etc., and smooth throughout.

He should turn for a long time, whether it be by the lathe or bow, exclusively with the point of a square, or lozenge-shaped graver, the end of which is ground off on a slope; this is the only possible method of learning to turn true, and it enables the workman to acquire great delicacy of touch.

Owing to carelessness, or to the fact that, when first beginning, they were set to work on metal that was too hard or rough, most learners turn with gravers that are ground to very blunt points; as the graver bites less, they are obliged to apply a proportionately increased pressure, and only succeed in tearing the metal away, subjecting it to a kind of rolling action, and rendering the hand heavy. If a pupil will not practice turning with the graver point, so as to preserve it intact for some time, dependent on the nature of the metal, he will never be able to turn perfectly true.

The bow should be used through its entire length, and with a motion that is progressive, not jerky. The knack of the turner with the bow consists mainly in keeping the simultaneous actions of the two hands quite distinct; one drawing the bow downwards, while the other depresses the point of the graver supported on the =T=-rest, and these two movements of the hands must be performed at the same time, but quite independently.

Irregular and sudden depressing of the graver point, or engaging it too deeply, causes its frequent rupture. This also sometimes arises from the fact that the point is not removed with sufficient rapidity, so that on raising the bow the metal catches it while traveling in the reverse direction; the graver is thus drawn slightly towards the work, and its point will be found too close in when the bow again descends.

As has been already observed, the bow, which must not be too short, should be used to its full length with a regular, but not rapid motion. Afterwards, when the hand has learnt how to manage the graver, the speed can be gradually augmented. There is always a danger of losing time, teaching, and, therefore, money, if pupils are too much hurried in their lessons. Before trying to work quickly, they should, at any rate, know how to work fairly well.

Short and sudden movements of the bow will make the object turned jerk; it will be heated, and the sharp angles of the graver will jamb in the metal; thus there is less work done, although there is more noise, and this is done badly.

=227.= When sufficient experience has been gained in turning with the graver point, and a trial is made with the cutting edge, do not attempt to remove much at a time by pressing heavily, but take the metal sideways so as to remove a continuous thread, using all the points of the edge in succession and the entire length of the bow. The metal will thus be removed as a thin ribbon or shaving. When the hand has had some experience, it will be found easy to remove long strips, and the work can be done quickly, although there be no hurrying in the movement of the bow. These remarks are equally applicable to turning with a lathe.

=228.= Hardened steel that has been let down to a blue temper requires certain precautions. If the graver is found not to cut cleanly, it must at once be sharpened, and no attempt should be made to remove more metal by increasing the pressure of the hand, because the steel will burnish and become hard under a point or edge that is blunt, and the portions thus burnished are sometimes so hard as to resist the best gravers. The only way of attacking them is to begin at one side with a fine graver point which must be sharpened for each stroke; at times it becomes necessary to temper the metal afresh before it will yield. It is asserted that by moistening the point of the graver with petroleum it becomes more able to attack hard substances, and that a mixture of two parts petroleum and one part turpentine enables it to turn very hard steel with comparative ease. Indeed, for all turning it is a common practice to moisten the graver with oil, water, turpentine, or simply by introduction into the mouth.

We have frequently seen apprentices, and even watchmakers, themselves, careless as to the proper sharpening of their gravers and thinking that they could hasten their work by the application of considerable pressure; they thus produced bright spots that required several hours of work before they could be removed.

There is one essential condition for ensuring good work with the lathe, and this consists in the perfect roundness of the points or holes of the runners or centers, and of the holes or points that are supported in them; this perfect truth is nevertheless very rarely met with, for it is noticeable that barely one watchmaker in ten knows at the present day how to roll such a point. We shall subsequently indicate the precautions to be observed in order to secure this accuracy.

The diameter of ferrule is also to be considered; if it is too small, the bow will slip and the object will only rotate by jerks; if too large, it loads the object unnecessarily and the velocity of rotation is reduced, since for the same stroke of the bow the ferrule must make a less number of turns. Moreover, if it is of large diameter, only a light bow must be used, because otherwise the force applied would be excessive.

Swiss workmen—at least the great majority of them—turn with the right or left-hand indifferently. This is a very useful accomplishment easily acquired when young.

The working of various tools, such as the English or Geneva mandrel, and any lathe driven by a treadle, will be a great help in developing the sense of touch and in making it more certain.

But it must not be forgotten that, in order to turn well, the lathe must be well made and planned; without this, no accurate work can be done. The lathe is the first and most important of tools, and a great number of very serviceable accessories can be added to it, which, unfortunately, but few watchmakers know how to make properly. As a rule they content themselves with a simple pair of finishing turns on which but a comparatively small amount of work can be done.

Without committing the mistake of having a too great multiplicity of tools, let the pupil rest certain that a well-planned set of tools in good condition both facilitates and abridges his work and renders it more perfect.

PART IV.

TOOLS AND APPLIANCES.

WORKSHOP FITTINGS.

=229.= Before proceeding to describe the various forms of lathes and the several small tools that the watchmaker should make for himself as occasion offers, either during his apprenticeship or immediately after, with a view to increase his manual skill or to extend his experience, it will be well that he take note of the principal conditions that should be satisfied by the ordinary tools that he will have to buy, as well as the precautions to be observed in their use and some improvements of which they are capable.

=230.= =The bench or board.= This should be fixed in front of a large window that affords a good light. The various hooks, recesses, etc., for holding files, hammers, etc., as well as the drawers, should be well in sight, not only in order that the hand can at once take hold of whatever tool is required, but also to enable the workman to restore them to their place immediately after use. By doing so he will have no occasion to retain on the bench any but those tools that are very frequently or continuously used.

It is an excellent habit, conducive both to well-planned and rapid work, and which can be easily acquired by a little attention during an apprenticeship, to always place the same tools in the same places, as the bench will then never be encumbered. By this means loss of time in turning over a number of objects in order to find one that may be small is frequently avoided.

This observation is of minor importance to specialists who require but a small number of tools; but it is of the first importance to a workman that is engaged in the repair of watches.

=231.= =The stool.= Those with cane seats are to be preferred. The height of the bench and stool should be so related that the muscles of the chest are not too much cramped, especially if the workman is engaged on an operation that occupies a long time and obliges him to maintain a stooping position. The stool with a screw is advantageous in this respect.

=232.= =The lamp.= Certain precautions in regard to artificial light have already been indicated in article =218=.

=233.= =Oilstones.= It is impossible to maintain the points of gravers in good condition if care is not taken to keep clean and flat the surface of the stone on which they are set; if it has suffered irregular wear, the level may be restored by rubbing the stone on a flat, smooth board, covered with a thin paste of fine sand and water. Most kinds of oil thicken on the surface rapidly, when the graver will slide over without being ground down at all, turning around in the hand and thus destroying the flat face and wearing the softer parts of the stone, rendering it uneven. A strong solution of potash or soda is very effective for removing this gummy mass; benzine is also recommended for the same purpose. Various substitutes for common oil are used; such as the mineral lubricating oils or petroleum. Dr. Latteux advocates the use of a mixture of alcohol and glycerine, the proportion of the latter decreasing as the extent of metallic surface in contact with the stone at once increases. Thus, for example, in setting a razor the stone will bite better if alcohol be in excess; but for a graver, of which only a small surface touches the stone, the amount of glycerine present should be relatively much greater.

=234.= =Circular oilstones.= Circular oilstones will be found very convenient for sharpening drills, gravers and other cutting tools, where it is desirable to have exact angles. An Arkansas or Turkey stone dressed down to circular form, and say 1½ inches in diameter, when mounted for the lathe will be found very useful. Apply the lubricant to the stone the same as you would to a flat one, and hold your graver or drill at the exact angle you wish the cutting edges to be and turn at a moderate speed. Truer angles and better work can be produced in this manner than by any other. Emery or corundum wheels can be mounted in a similar manner. Small circular stones can be obtained from material dealers and dental supply houses, in sizes varying from ½ × ■ to 3½ × ¾ inches. They can be mounted similar to Fig. 49, by turning down a piece of No. 30 Stubb's steel wire to the size of the opening in your wheel and riveting the wheel firmly upon it. The best sizes for watchmakers' use are ½ inch, 1 inch and 1½ inch in diameter.

[Illustration: _Fig. 49._]

=235.= =Small grindstones.= When it is necessary to remove a good deal from the face of a graver, the operation will take too long on the oilstone, and there would be considerable difficulty in maintaining the flat face; recourse must then be had to the grindstone, but it should be remembered that care is needful when using it. The grindstone must always be thoroughly wet in order to avoid heating the graver, as its cutting power would then be destroyed. The emery wheels described in paragraph =165= can be used for this purpose, but they are, for the most part, inconvenient on account of the rapid increase they occasion in the temperature of the metal. Some forms of emery wheel can, however, be moistened just as the grindstone.

When the cylindrical surface is rendered irregular by use, take a piece of sheet-iron, the tail of an old file or a cold chisel, and hold it with one hand firmly on a support against the edge of the stone, which is rotated by the other hand. The surface can thus be made smooth and true, providing it is only attacked gradually and the handle is not turned too rapidly. An excessive velocity will heat the iron, which is then less effective and is more rapidly worn down; whereas, with a slow motion, the iron will relatively wear little and the stone more. A rough diamond mounted at the extremity of a steel rod, affords an excellent means of trimming a grindstone, and is at the present day generally used in factories.

=236.= =Glasses.= Some particulars have already been given in regard to these simple microscopes in article =218=.

=237.= =Files.= A new file should never be used for steel; it is best to employ it for some time at first on brass, taking care not to use it too roughly. If employed to steel at once, or if sharp, quick strokes are applied, the cutting edges of the file will chip off, and the hard particles will be embedded in the metal operated upon; the work will thus be bad, and the file itself deteriorated. A file that has been carefully used, and has passed gradually from brass to steel, will last four or five times as long, and will always work well.

Watchmakers often fit files into handles by driving them firmly into round holes in the handles; this practice frequently leads to the handles being cracked, and the following method is preferable: Take an old worn out file or a piece of iron of the same form as the tail of the file to be fitted; heat it several times to bright redness and drive it, when so heated, into the handle, taking care to maintain it perpendicular. A hole will thus be made of the required form, in which the file will hold without there being any occasion to apply excessive force in fixing it in position.

When the surface of a file is choked with particles of iron, copper, wood, etc., while the cutting edges are yet good, it can be cleaned as follows: Place the file for a few seconds in a hot lye of potash in water, and on withdrawal, dry it before the fire and brush the surface with a stiff brush.

=238.= To renew the cutting edges of files, either of the following methods can be adopted: 1. First clean the file with potash or soda dissolved in water, if greasy or resinous substances have to be removed; with hydrochloric acid if it is rusty; and by rubbing with a metallic brush or piece of coke if particles of iron, brass, lead, copper or tin have to be removed. The file is now immersed in a mixture of 1 part nitric acid, 3 parts sulphuric acid, and 7 parts water. As the action of the acids become less energetic owing to the combination with iron, the temperature of the mixture must be raised, since rapidity is a condition of success. The time during which the file should remain in this bath varies from 10 seconds to 100 or more, the roughening of fine-cut files being far more rapid than when they are of a coarser cut. On removal from the bath, immerse in lime wash, dry, and then cover them with a mixture of oil and turpentine by means of a brush, after which they are ready for use. 2. After being cleaned, as explained above, the file is supported in a dish full of water, resting on two cross wires, so that all its surface is in contact with the liquid. Now add strong nitric acid in the proportion of 1 part to 8 of the water, mix it thoroughly and allow it to remain for 25 minutes. Remove the file, and, after washing in water and rubbing with a hard brush, place it again in the bath, to which a second eighth part of acid is now added, and leave it for 50 minutes. Again remove and brush the file, add a sixteenth part of concentrated sulphuric acid, and replace the file in the bath. Then wash successively in pure water and in lime wash (to remove the last traces of acid), and dry. The file will be found to possess both the qualities and the appearance of a new one.

=239.= _To cut an equaling file._ It often happens that a workman is called upon to modify the shape of, for example, the bottom of a rectangular notch, and he is not provided with a file of suitable shape. In such a case he can adopt one of the following methods of extemporizing a file:

[Illustration: _Fig. 50._]

1. Clamping the small steel strip, L, Fig. 50, in a vice, cut the notches with a chisel, _n_, as follows: Holding _n_ a little inclined, cut the first notch, _i_. This will slightly raise the metal, presenting a rounded face at the back. To make the next cut, hold the chisel with its edge on L and, after drawing it backward until arrested by the back of _i_, incline it to the requisite amount and give a second blow with the hammer, then continue the operation till the whole is finished. A few trials will enable any workman to make a small file with sufficient accuracy for his purpose.

2. Employ an arrangement similar to that of the micrometer divider (=44=) only more rigid. A study of this article and examination of the corresponding figure will afford all the information that is necessary.

3. This is identical with the method of dividing a rule described in =46=, except that the divisions are closer together and the tracer is replaced by a revolving cutter with its axis a little inclined, to give the requisite slope to the teeth of the file. This cutter is supported in a hinged frame and provided with a washer of ivory or other such substance, as seen at _s_, Fig. 50, to determine the depth of cut.

=240.= _Beaupuy files and burnishers._ Most watchmakers are acquainted with the files and burnishers that M. Beaupuy has introduced for rapidly forming conical pivots, the main characteristic of which is that the corner presented to the pivot is rounded to the desired form and roughed; they do their work rapidly and well, but some skill is necessary in their management. To the

instructions which accompany them we would add the following:

They must never be used when quite new on a pivot that is to be employed in a watch; it will be reduced too rapidly. The freshness must be worn off the cutting edges of the teeth by preliminary use.

The pressure must only be applied perpendicularly to the surface of the staff as in making a square-shouldered pivot; the file is held against the flat surface without pressure. A lateral force will have the effect of straining the pivot and causing it to break.

=241.= =Pliers, tweezers, etc.= It is advisable to have a considerable number of these, as their strength should always be proportional to the force that has to be applied to them. For example, if a pair of sliding tongs is used when a hand-vise is needed, the former will be strained beyond its limit of elasticity and the tool becomes nearly useless.

The same might occur with any other form of pliers or tweezers. In the hands of a good workman they will last for a long time, but if used unintelligently, without proportioning the size of tool to the force that has to be applied, taking up the first that comes to hand, all the tools will soon become unsatisfactory and the work itself will suffer. It is very desirable to have one or more pairs of brass pliers and tweezers for handling metal work without the risk of scratching.

=242.= =Compasses, gauges, micrometers, etc.= The common compass for measuring thickness, the douzieme gauge, is not always strictly accurate in its indications. The douzieme proper, has a scale divided into twelfths, though some patterns are now made that have a scale divided into tenths and hundreds of an inch and again there are others that measure the fractions of a millimeter. The greater majority of these tools on the American market are correctly divided, but we sometimes come across those of foreign make that are divided incorrectly and care should be used in selecting. In the inaccurate tools the objection is that the opening of the jaws gives a measure of a _chord_ whereas the displacement of the index measures the _arc_ of a circle. It follows from this, that, if the index is first arrested when pointing to 15, for example, and again when at 30, the interval between the jaws in the second case will not be exactly double the first. Before purchasing, it is well to test the gauge for accuracy in this regard by some reliable standard.

=243.= _Caliper for mainspring height, depth of sink, etc._ A simple instrument for taking such measurements is shown at G, Fig. 51.

[Illustration: _Fig. 51._]

The finger _a_ travels over a graduated arc whenever the rod _c_ is pressed inwards; _b_ is a fixed stop, with its extremity in the plane of _n_. Any movement of _a_ below _o_ measures the space traversed by _c_ within the line _b n_.

Laying a coiled mainspring, for example, on a plane surface, stand the base _n_ of the caliper upon it, and the end _c_ pressing on the table will be forced upwards and move the needle. To take the depth of a barrel, press _c_ on the bottom, allowing _b_ to rest on the edge of the cover recess.

It will be evident, from the figure, that _a_ and _c_ are connected by a spring passing around drums at corresponding axes. The smaller _j_ is, the more sensitive will the instrument become.

=244.= =Figure 8 caliper.= For ordinary work, the calipers to be bought at material stores will suffice; but when it is required to verify escape wheels, balances, etc., there is some risk of accidents in consequence of the variableness of the friction at the joint. To remove this source of danger, true the rubbing surfaces in the mandril and replace the brass discs at the center by similar discs of steel, then carefully re-make the rivet that forms a hinge, after oiling all the acting surfaces. The arms will now move with a uniform degree of stiffness, so that there need be no danger of jerks.

=245.= =Riveting stake and punch.= The holes in a riveting stake are made to increase downwards, so as to avoid any accident occurring through the oscillation of the axis. The riveting punches made of a plain steel rod, with a hole drilled at one end in the direction of the axis, are the best. Those that are perforated transversely like the lanterns of screw-point tools, do not produce such good riveting, since the parts of the end, from behind which metal has been removed, are more or less elastic.

=246.= =Burnishers.= Burnishers will not remain in good condition unless their surfaces are prepared, from time to time; in the case of those used for very fine work, by passing over a buffstick charged with polishing rouge or very fine emery, and other kinds on an emery stick more or less fine, according to the degree of roughness the burnisher is required to possess.

=247.= _To re-face a burnisher._ Pivot burnishers are usually re-faced by a lapidary; a watchmaker can, however, do it for himself very effectually in the following manner: Prepare a dry, smooth piece of wood, rather thick, and of a width equal to the length of the burnisher. On this board carefully glue a piece of emery paper, of a fineness corresponding to the degree of cut required, stretching it as even as possible, and turning the edges down towards the under side. Then lay the board on a firm smooth surface, resting a weight upon it, and allow it to dry.

In using this lap, it is fixed or allowed to rest against the side of the bench; holding the burnisher with two hands at its extremities, the workman places himself at one end of the board, and draws the burnisher along it towards him, maintaining the surface quite flat and applying considerable pressure. On reaching the nearer end, raise it, and after again placing it on the farther end, draw towards the body, and so on.

By proceeding in this manner and always in the same direction, placing the burnisher so that the acting edge is farthest away from the operator, all risk of rounding this angle will be avoided.

=248.= =Broaches.= Great care is needed in adapting handles to broaches. Resting the point against a finger of one hand and causing the handle to rotate by two fingers of the other hand, the broach itself should be seen to remain true.

It is a good precaution, suggested by M. H. Robert, to gently draw a piece of iron, charged with rouge, along the edges of pivot broaches in order to remove the thread of metal from them. Minute particles of this thread would otherwise remain in the holes, and occasion wear of the pivots.

These fine broaches are not fixed in handles, but a piece of sealing-wax is melted on to the upper end; then, holding the broach between the fingers, with its stem downwards, it is rotated while held to a flame, so that the sealing-wax forms a regular, oblong handle.

=249.= =Blow-pipes.= In order that a long even flame may be obtained, the hole should be of moderate size and perfectly clean around the edge; otherwise the jet cannot be straight and sharp. Difficulty will always be experienced by anyone who has not learned to breathe without interrupting the continuity of the blast. Where a supply of gas is available, the gas blow-pipe presents advantages from the point of view of convenience.

[Illustration: _Fig. 52._]

Fig. 52 shows a gas blow-pipe for jewelers, which is simple and convenient. It consists of a blow-pipe of the ordinary form, having a gas pipe inserted in the lower half, and a threaded hood or sleeve at the lower end, which changes the shape of the flame by screwing in or out, so as to vary the influence of the current of air upon the flame. A ring adapted to slip over the finger while working, is soldered to the middle joint of the pipe, and the quantity of gas is controlled by the stop-cock and spring lever shown in the cut, the gas being supplied to the pipe by a rubber tube connecting it to the nearest gas jet in the usual way. Thus having the shape of the flame under control and the quantity variable at will, the workman is in position to accomplish the desired end speedily and effectually.

To use to the best advantage, set the jamb-nut so that with the valve lever in its normal position, the flame at the end of the pipe will just keep alight. The blow-pipe can then be laid down temporarily and again used without the trouble of turning off the gas or relighting.

When used as a mouth blow-pipe, the most convenient way to hold it is with the third finger through the ring. For bellows work it is better to pass the ring over the index finger. The ring also serves, with the valve-lever, as a rest to hold the flame-nozzle away from the table when the blow-pipe is laid down temporarily.

To produce an oxy-hydrogen flame, connect the air-pipe with a cylinder of nitrous oxide, opening the cylinder-valve carefully, so as to permit the escape of only sufficient nitrous oxide to produce with the illuminating gas a very small flame. Regulate the illuminating gas flow with the thumb-screw or with the finger on the lever of the blow-pipe valve.

[Illustration: _Fig. 53._]

Fig. 53 shows an automatic hand blow-pipe for use with a foot blower. One of the rubber tubes shown is connected with the blower and the other to the gas supply. It is self adjusting for both gas and air, requiring only a slight motion of the lever, shown under the

thumb, to obtain instantly any flame, from the smallest to the largest; so that these pipes have all the delicacy of the best mouth blow-pipe, used with the utmost skill, together with the power and advantages obtained with a mechanical blower.

=250.= =Small gas furnaces.= The workman will frequently have occasion to anneal pieces of steel or to raise to a red heat objects that are too large for the blow-pipe; an ordinary open fire aided by bellows is often resorted to in such a case. A better plan, however, is to use any small portable gas furnace, provided with a hood that completely closes it at the top.

Fig. 54 shows a gas melting furnace, which is kept by material and supply houses. It is powerful enough to melt gold, silver, brass and copper, but is not recommended for cast iron. It can be used for scorifying and cupelling. The lid can be pushed sideways sufficiently to give access to the interior of the furnace.

[Illustration: _Fig. 54._]

The following points in the management of a gas furnace will be of service to all novices in their use. The power and speed are practically without limit, depending only on the gas and air supply, and are under perfect control. Allowing five cubic feet of gas for heating up, it requires about four feet of gas for every pound of cast iron melted. For small work it is as cheap as a coke furnace, and not one-quarter the trouble.

The quantity of air required depends upon the gas supply. One must be equal to the other, so that perfect combustion will take place, and that entirely within the furnace. An excess of either gas or air renders a high temperature an impossibility.

See that all gas taps have a large clear way through. High temperatures and rapid working require a free supply of gas.

To adjust a new furnace to its highest power, connect both gas and air supply with the burner. Turn on the full gas supply, light the gas, the air-way being full open, work the foot blower and then put the gauze nozzle of the burner tight against the hole in the casing, so that no flame escapes around it. If the flame comes out of the lid about two inches, the adjustment is right. If the flame is longer, open the air check until the proper flame is obtained, or reduce the gas supply. If smaller, or not visible, close the air check until the flame appears.

The cap-nut, which will be found at the throat of the horizontal “mixing tube,” where the air enters and mixes with the gas, is used for changing the size of the orifice from which the gas escapes. When the escape is from a large orifice, a smoky, yellow, or “reducing” flame is the result. By contracting the orifice by screwing the cap-nut on to the gas delivery tube, a blue or oxidizing flame will be obtained. Adjustment for the proper flame should first be made by this nut, and the size of the flame regulated afterwards by means of a cock at the gas main. A slightly yellow flame gives the best results when a high heat is desired. The arrangement above described is clearly shown at the left-hand lower corner of the sectional illustration above.

A chimney or stove-pipe 8 or 10 feet high may be used as a fixture, and the draft partially stopped by the damper or slide when lower temperatures are required, the gas being turned down in proportion; the guide for the proper adjustment being that UNDER ALL CIRCUMSTANCES THE FLAME MUST JUST COVER THE CRUCIBLE OR MUFFLE, but not extend into the chimney so as to make it red hot. When the flame covers the crucible or muffle, the gas is doing its extreme duty under the most favorable circumstances, without waste.

Keep all fluxes away from the furnace jacket, as they are injurious to fire clay, and are liable to cause the lids, etc., to stick to the furnace.

A thin layer of quick lime on the bottom of the furnace will prevent the crucible adhering to it when very hot.

When using a furnace for high temperatures, care should be taken not to use a fire clay casing, as it melts at a temperature a little above that of cast iron; plumbago or asbestos only should be used when very high temperatures are required.

[Illustration: _Fig. 55._]

Fig. 55 represents a small gas furnace, which is extremely useful for small meltings, experimental work, etc. It consists of a pot made of a mixture of fire clay and asbestos, bound with rivetted iron hoops, and having a hole in the side at which the flame enters. A lid pierced by a central hole permits the escape of the products of combustion, and the crucible is placed in the center so that the flame surrounds it. It is worked with gas and a foot blower. Gas from a ■-inch supply pipe will work it efficiently. About ten cubic feet of gas per hour is sufficient for most purposes.

The casing holds the heat so perfectly that the most refractory substances can be fused with ease, using a Fletcher foot blower. Half a pound of cast iron requires from seven to twelve minutes for perfect fusion; the time depending on the gas supply and pressure of air from the foot blower. The crucible will hold about ten ounces of gold.

The power which can be obtained is far beyond what is required for most purposes, and is limited only by the fusibility of the crucible and casing.

[Illustration: _Fig. 56._]

Fig. 56 represents a small apparatus, which, owing to its speed and economy of operation, has a very extended use in the jewelry and silversmithing trades. With this apparatus a sound two-ounce ingot of gold or silver can be moulded in two minutes. A crucible of moulded carbon is supported by a sheet-iron slide, or plate, which is clamped to an ingot mould by a clamp which swivels in the U-shaped cast iron stand. The metal to be melted is placed in the crucible, and the flame of the blow-pipe directed on it until it is perfectly fused. The whole is then tilted over by means of the upright handle at the back of the mould. The waste heat serves to make the ingot mould hot. No flux should be used with the carbon crucibles. For the smaller operations, such as making small quantities of colored golds, for electroplating solutions, testing ingots, and the smaller operations of the jeweler and plater, it is invaluable.

[Illustration: _Fig. 57._]

The air pressure used in operating gas furnaces varies from one to four pounds per square inch, though the latter is seldom required except for the severest work in large furnaces; as a general rule it is less than two pounds in the operations of the gold and silversmith. The pressure must be arranged so that the air supply equals that of the gas used. This can be readily seen by the color of the flame, as noted in instructions for handling the furnaces. For small operations foot blowers are used. These consist of a powerful bellows having a hemispherical pressure chamber on one side, and adapted to work either by the hand or foot; see Fig. 57.

[Illustration: _Fig. 58._]

[Illustration: _Fig. 59._]

The perfect combustion of the gas is secured by mingling equal quantities of gas and air in a mixing chamber, and then igniting the mixture. In the larger furnaces this is accomplished by a mixing chamber placed under the furnace, so as to heat the mixture before ignition, and no pressure supply of air is necessary. In the smaller apparatus, this mixing is done in the burner, which consists of an inner tube carrying an air supply, surrounded by a gas tube, and the whole surmounted by a sliding nozzle for changing the shape of the flame. The mixing chamber being so small, the air and gas pass through it so rapidly that considerable pressure of air must be provided to prevent it from being excluded by the normal pressure of the gas; hence the necessity for a blower when using small burners.

When it is not desirable to use gas, for pecuniary, or other reasons, melting may be carried on by means of a gasoline gas flame, which is noisy, but otherwise little inferior to coal gas. The furnaces for gasoline differ but little in construction from the others, as will be seen by Figs. 58 and 59. The only difference being that the burners are applied from the side and no air pressure tubes are needed, while the furnace is supported on legs to insure safety from fire.

[Illustration: _Fig. 60._]

The burner for gasoline is radically different from that for gas, being, in fact, a small gas machine, Fig. 60.

In Fig. 60 _P_ is an ordinary force pump, at the bottom of which, at _A_, is a valve which closes automatically upon releasing the pressure from the pump, _C_ is a check valve which closes the inlet to the tank _T_ completely; _F_ is a filling screw for introducing gasoline. _V_ is a vent screw for letting off the pressure when through; _H_ is a pipe leading from the tank to the burner _D_; _E_ is the burner regulator, terminating in a fine point, closing the orifice of the burner; _S_ _S_ are packing boxes. Upon opening _C_ and pumping a few strokes a pressure is created in the tank and on top of the fluid, forcing it through the tubes of the burner, which being previously heated, vaporizes the gasoline. This issues from the orifice at the end of _E_ as a highly heated gas and burns as such in the form of a powerful blast, Fig. 61. After being once started the heat of the flame passing through the burner, vaporizes the fluid in the tubes, and hence the apparatus is automatic.

[Illustration: _Fig. 61._]

The air which is forced in is not consumed, so that to keep up the blast it only requires a few strokes of the pump occasionally to maintain the pressure lessened by the consumption of the fluid.

To operate the blow-pipe: close _E_; unscrew _F_, and introduce from two quarts to one gallon of gasoline of 76° according to the capacity of the tank. Replace _F_ and close _V_; open _C_ one or two turns and give three or four full strokes of pump _P_, and close _C_. Heat the burner by burning some of the fluid in a suitable vessel placed under the burner; when hot enough apply a match and open _E_ gradually, until the action is more or less uniform. If no spray or liquid issues from the orifice, the burner is hot enough; if not hot enough, burn slowly until no liquid or spray issues. When sufficiently heated the blast can be made of any intensity desired, by the use of the pump as above. To stop its action, shut the regulator _E_, or open screw _V_, or both. When not in use the vent _V_ should invariably be kept open. The mouth of the burner _D_, should be two or three inches from the inlet of the furnace, or there will not be perfect combustion.

For very high temperatures and muffle work, light the burner as above and heat the inside of the furnace to a bright red; then place the burner against the inlet of the furnace; turn out the burner by means of the cock _E_, and immediately turn it on again without lighting it, when if the furnace is hot enough, the gas will ignite inside the furnace. The heat can be regulated as in the first method of burning. When burning inside of the furnace, there must be no flame in the burner tube; it should all be inside the furnace, and the tube of the burner must be close to the fire hole, or there will not be enough heat in the tubes.

Use a drop or two of sperm oil on the piston of the pump occasionally, also on leather washer at _F_, otherwise the apparatus will be apt to leak, corrode and work badly.

[Illustration: _Fig. 62._]

=251.= =Muffle Furnace.= This consists of a fire-clay furnace, mounted upon a powerful gas burner and containing an oven, also of fire-clay or plumbago, so placed as to receive the full heat of the flame, without permitting the direct action of the flame upon any object placed within it. The objects are placed in and withdrawn from the muffle, or oven, through the door shown in the cut. This door is made of two pieces so that the upper one may be removed to watch the progress of the work without chilling the contents of the muffle by too great an entrance of cold air. They are extensively used for assaying, annealing, etc., and for many other purposes where an exact temperature is required. The illustration shown in Fig. 62, is of a gas muffle, but they are also made to be used with the gasoline burner previously described.

THE LATHE.

=252.= Of all the tools and machinery employed by the watchmaker, the lathe is the most important. Very poor work is often turned out by those possessing a first-class lathe, but there are very few persons who can turn out good, true work, from a poor, cheap lathe, and if it is untrue it is utterly impossible to turn out good work. Wonders can be accomplished by the ingenious mechanic who thoroughly understands the capabilities of the lathe. By patient skill of manipulation, the Chinese and Japanese turn out some truly wonderful work; they succeed in turning sphere after sphere, one inside the other, from a solid piece of ivory, the opening from one to another being comparatively small.

The earliest form of the lathe in the trade was the dead center: that is, a lathe whose parts did not revolve, the object to be operated on being placed between centers and made to revolve by means of the bow. This form of lathe was succeeded by the live spindle or live mandril pattern, although there were many good points about it that must be acknowledged. It contained one great element that many modern appliances, termed lathes, lack, i. e., the element of truth. No matter how coarsely or crudely constructed, this truth was not eliminated, except by the ignorance of the artisan, for the centers must remain the same relatively, whatever may be their position in relation to the lathe bed.

With the introduction of the live spindle lathe in this country, the verge, Jacot and other lathes and tools of that type were rapidly abandoned. In Europe, however, the live spindle lathe did not meet with such a cordial reception, and it has taken many years, in some localities, to overcome the prejudice against them; in fact, there are still many workmen there who cling to the dead center patterns.

The all-important point in lathes of the live spindle type is accuracy of fitting, and particularly in regard to the spindle and its bearings, for unless a certain degree of perfection is attainable in this particular, it is worse than useless, as it not only does not do

the work, but leads the artisan astray. The workman, sometimes, through motives of economy, purchases foreign made lathes, that closely resemble the American in outline and finish. These lathes, as a usual thing, are not accurate, and in the greater majority of cases the chucks which accompany them are worse than nothing, and yet these lathes, in nearly all cases, are declared to be as good as the American. There are some foreign lathes that are very carefully made, and are quite as true as the best American, but they are the exception and not the rule. The workman who buys one of these lathes cannot, of course, tell whether it is right or wrong until he has placed it on his bench and tested it, and even then he cannot be sure, for although when a certain chuck is placed in the spindle and tested it may apparently show no deviation from truth, there may still be untruth in the spindle or chuck or both, as the errors in one may be counteracting the errors in the other, and if the chuck be turned or an absolutely true chuck placed in the spindle, the error will be made quite apparent. If an American lathe, by any possibility, is allowed to pass the inspector, and finds its way upon the market, the maker is only too glad to replace it with a perfect one, for his reputation is at stake; but if one of the imitation pattern proves untrue you will have to do the best you can.

[Illustration: _Fig. 63._]

There are American made lathes upon the market that are as inferior in many respects as the imitations, and the watchmaker will do well to do without a lathe until such time as he can afford to purchase one of known reputation. Among the first-class American lathes upon the market may be mentioned the Webster-Whitcomb, shown in Fig. 63; the Moseley, shown in Fig. 64; the Hopkins, shown in Fig. 65, and the Rivett, shown in Fig. 66, and others.

An excellent lathe for the heavier work of watchmakers and jewelers, such as cannot be performed with satisfaction on the watchmaker's lathe, is the No. 4 Barnes, which is shown in Fig. 67.

[Illustration: _Fig. 64._]

For screw-cutting, the manufacture of watchmaker's tools, fishing reels, repairs on tower clocks, in fact, all the heavier work of the trade, it is admirably fitted.

=253.= =Care of the Lathe.= The American lathe of to-day is a marvel of completeness in its parts, and how many hours, yea months, of study and experiment have been bestowed upon it by its projectors and makers to acquire these points of utility and excellency? What a vast amount of care has been exercised for the production of a perfect lathe! Must this care cease at the moment it passes into the hands of the watchmaker?

It is a very easy matter at any time to wipe off the dust and oil that may accumulate, but does this alone constitute due care? There may be a nice glass case to cover it and keep off the dust, and a very good idea it is, if faithfully used; but if a counter shaft is on the bench, or much lathe work is to be done, it soon falls into blissful desuetude, or finishes its usefulness by being broken. Then, often, a cloth is wrapped about the lathe, which soon gets soiled and looks badly, let alone the poor protection it affords.

[Illustration: _Fig. 65._]

Dust is omnipresent, and the greatest enemy to all active machinery; it insidiously makes its way into every crease and crevice, and if not promptly removed will cause untold damage. We cannot get rid of it and must (like the industrious housewife) wage a constant warfare against it.

The care necessary to be given to a fine lathe differs from most other tools; it is not confined alone to the removal of dust and keeping clean, but the fitting properly of the several parts as used. There should be no overstraining when tightening screws, chucks, etc., or when fitting articles in both wire and wheel chucks, and so on through the list.

[Illustration: _Fig. 66._]

The face of the lathe bed when it comes from the makers is (or should be) perfectly true from end to end, in order that head and tail stocks will meet on a direct line of centers, even should they be changed end for end, and a good lathe will meet those requirements. Now, it is obvious to any thinking mind that if this face becomes injured by neglect, whereby the nickeling is removed in spots or portions, they will, in all probability, become rusty; this rust will then eat away and throw off more, and soon the face presents an uneven surface, which will tend to destroy the line of centers between head and tail stocks.

The head stock, usually occupying one position, causes less wear at this point or place, while the hand-rest and tail stock are constantly being shifted, so where there is more motion or action there must be more wear, especially if dust, chips, or grit be

allowed to accumulate beneath them, and though the wear is seemingly imperceptible, it nevertheless is there, and will sooner or later manifest itself, and this is a signal that the level of the bed is becoming impaired, and, necessarily, the truth. Thus too much care and attention cannot be exercised in guarding against chips and dust when sliding hand-rest back and forth on the bed.

[Illustration: _Fig. 67._]

At the end of the bed, where the tail stock takes position, many watchmakers have the tail stock off, and this portion is more exposed to atmospheric action, also receiving perspiration from the hands when they come in contact. Again, others let the tail stock remain in position, only removing when it comes in the way. In the former case, it is well to devise some means for the protection of the bed; this is easily done by making a sheath of chamois skin to slip tightly over the bed; it can be removed and replaced readily, and when it becomes soiled, can be washed.

This sheath should be fully two-thirds the length of bed, or reaching from tail end up to hand-rest when it is close to head stock. It preserves the bed from dampness, which is considerable in some climates, also the perspiration of the hand and flying chips and dust. In the second case, if the tail stock is allowed to remain on the lathe, or, if removed and placed on the bench, it is subjected to all the evils the bed is in the former. Our opinion is, the tail stock should be kept in its compartment in a tight-fitting drawer, away from dust and accidental knocks of other tools on the bench; the tail spindle not being nickeled, is more liable to rust if left exposed, and should be kept in a sheath of oiled paper. This may seem superfluous and too much bother, yet it is taking proper care which tells in the end.

The bottom of tail stock should always be brushed off before placing in position, not only for its protection, but for fear some particle of grit may be adhering, thereby throwing it out of truth, and screwing it down tight only adds injury to the lathe if allowed to remain.

The head stock demands close attention; the spindle should run freely without end-shake, and about once a week should be speeded, meanwhile administering oil until it leaves the bearings clean, and then wiped off. A little oil should be added every day. See that the mouth of the spindle is kept bright and clean; thrust a piece of cloth clear through spindle every now and then, that all dust and dirt may be removed.

Wire and wheel chucks should often be washed in gasoline to remove gummy dirt and oil which is constantly adhering, and it is even well each time a chuck is used, to wash off first, then wipe dry. A little dirt on the mouth of spindle, or on the chuck, often throws it out of truth, and consequently the article fastened therein also.

When fitting head or tail stocks, or in fact any attachment, do so carefully. Do not bang it in place as if you held a grudge against it, and when in position see that they are tightly screwed in place.

Having too much end-shake on live spindle, especially in soft lathes, causes uneven wear in its bearings, besides not being reliable for true pivoting or any such work.

When the cost of a lathe is taken into consideration, it goes to prove that it is not easily replaced. Where is the jeweler with a stock of goods who would retire without first seeing that his valuables were in the safe, but how many are there that think of giving this protection to their lathes? Some do, but the greater per cent do not. It is a good plan to see that the head stock, the tail stock, and attachments are in the safe and should a fire break out that endangers the store, and no chance to save it, the feeling of satisfaction is great to know the lathe is safe, that is, the most expensive parts, for the bed can be purchased at a nominal cost compared to the attachments.

THE FOOT WHEEL.

[Illustration: _Fig. 68._]

=254.= In the selection of a foot-wheel the workman must be governed by his own experience and taste, for the variety that exactly suits one person is very distasteful to another. The swing treadle pattern shown in Fig. 68 is a very popular one with American workmen. These swing treadles are made in various ways by the different manufacturers, but the methods of using them are alike. There are workmen, however, who prefer the heel and toe motion and others that prefer the up and down motion. This is all a matter of taste and it matters but little what form of lathe wheel is used provided the motion is steady and the exertion is light. As a general rule a heavy wheel, say forty pounds in weight, will be found, on the whole, much better than a light one and the motion will be more uniform.

=255.= =Driving Bands and Belts.= Most foot-wheels are so constructed that either a flat or round belt may be used in transmitting the power to the countershaft or lathe, as the case may be. Many watchmakers use a flat belt between foot-wheel and countershaft and a round leather belt, or cord, between countershaft and lathe. If we may judge by appearances, this is the favorite fitting. Others use round leather belts in both instances, while others again use cotton or hemp cord or gut. All things considered, the round leather belt seems to possess advantages over all others. It does not slip as easily as cotton cord, is more elastic than gut and throws less strain on the bearings, absorbs less power and works much smoother. The ends are fastened together by means of an S hook and the cord may be readily tightened by giving it an additional twist or two.

[Illustration: _Fig. 69._]

=256.= =The Countershaft.= The countershaft is indispensable in using milling tools, wheel cutters and pivot polishers. The pattern shown in Fig. 69 is but one of many on the market.

In some of the patterns the uprights extend through the top of the bench and are held securely in place by means of thumb screws or wing nuts. The pattern shown in the illustration is mounted on a solid metal base which is intended to be fastened to the bench by means of screws. The advantages of using a countershaft are three fold: First, you are able to regulate your speed perfectly without changing the motion of the foot from fast to slow or vice versa; second, your belt is carried to the back of the bench, where it is out of the way, instead of coming down in front of the head; and third, you obviate the necessity of having holes in your bench on each side of the lathe, that small articles are liable to drop through. Fig. 70 illustrates the favorite arrangement of foot wheel, countershaft and belts.

THE BENCH.

[Illustration: _Fig. 70._]

=257.= As previously suggested (=230=) it is of the utmost importance in doing good work, and doing it rapidly, that your bench be kept orderly and clean at all times, and that all your tools and devices be in their proper places, exactly where you can put your hand on them at a moment's notice. An excellent arrangement for a watchmaker's bench is shown in Fig. 70. This bench was designed by G. W. Laughlin, and is complete in every detail. Benches can be purchased ready made from material dealers, both with and without curtain tops, but there are many watchmakers that prefer to make, or have made for them, a bench varying from the usual pattern. The bench illustrated is made of black walnut, veneered with French walnut and bird's eye maple. The top is 21 inches wide by 41 long and is 33 inches from the floor. The drawers on the right-hand side are 10 inches wide. In the center are two shallow drawers, while the left-hand side is entirely boxed in.

IDLERS.

[Illustration: _Fig. 71._]

[Illustration: _Fig. 72._]

[Illustration: _Fig. 73._]

=258.= Idlers are especially valuable for use on slide rest tools, such as pivot polishers, milling attachments, wheel cutters, etc., and with traverse spindle tailstocks, traverse spindle drivers, etc., to give a vertical direction to the belts. Idlers are constructed in various forms, some of them being mounted on upright posts, fastened to the bench just back of the lathe, as shown in Fig. 71; others consist of steel rods terminating in a ball, and socket joint, where it is fastened to the bench, as shown in Fig. 72, while in other patterns the rod is fastened by means of a wing nut to a brace running from one to the other of the supports of the countershaft and may be placed at any desired angle. The idler shown in Fig. 73 can be used in this way. Some watchmakers prefer to place their idlers on an overhead countershaft, which is usually fastened just back of the bench and about two and a half or three feet above it. The idler shown in Fig. 72 can be screwed to the bench or to the wall above the bench, in the latter case it will extend out horizontally over the lathe and is out of the way of the watchmaker when not in use. In the forms shown in Figs 71, 72 and 73 the belt passes from the countershaft over the idler and one long belt only is used. This style is sometimes varied by using two separate belts one from the countershaft to the idler and another from the idler down to the lathe. If in the latter style, a cone pulley of rubber is used on the countershaft and also for the corresponding pulley on the idler and a plain pulley for the down belt. Of course in this form the idler stand must be in the form of a countershaft, as the pulley must be fast on the shaft and the shaft

itself must revolve. In the styles shown above, the shaft is rigid and the pulleys revolve upon it. The advantage of using the cone pulley style is that the speed of the cutter or other attachment may be varied at will without in any way increasing or decreasing the speed of the wheel.

CHUCKS.

[Illustration: _Fig. 74._]

[Illustration: _Fig. 75._]

[Illustration: _Fig. 76._]

[Illustration: _Fig. 77._]

[Illustration: _Fig. 78._]

[Illustration: _Fig. 79._]

=259.= True chucks are the most important adjuncts to a watchmaker's outfit. A true lathe with poor, untrue chucks is almost useless. Chucks hold the work truest that comes the nearest to fitting the holes in them. If you try to hold work in a chuck that is too large or too small, you will soon get the chucks out of true and you will soon become dissatisfied with your chucks, your work and your lathe. Care should always be taken to select a chuck that will take the work without straining it open and yet is not so large that undue pressure will have to be used in holding it. The American split chuck, when true, will hold almost any piece of work with the greatest precision as regards truth; but the split chuck is a delicate attachment and will not stand hard knocks and rough treatment. After using them, you should clean them in benzine to remove all dirt, rinsing them in alcohol and drying with a soft linen rag, and see that no small chips of metal are left in the openings that may throw the work out of truth the next time they are used. Fig. 74 illustrates the regular pattern split chucks that accompany American lathes. Fig. 75 is a conoidal wire chuck, so called because the shape of the mouth of the chuck is conoidal in lieu of the shoulder usually left on wire chucks for the bend in the spindle. Fig. 76 is an arbor chuck. This is a solid chuck on the end of which is a threaded arbor for the reception of saws, laps, wheels, etc., which are held firmly in position by means of the nut on the threaded arbor. Fig. 77 is a screw chuck. This is a solid steel chuck having a threaded hole in the end for the reception of cement brasses, etc. Fig. 78 is a shoulder chuck. It is a split chuck with a large opening in the end with square shoulders for the work to rest upon. Fig. 79 is a taper chuck, which is solid and has a large opening for the reception of tapers, centers, laps, etc. Fig. 80 is a step or wheel chuck, which usually comes in sets of five, and as each chuck has nine steps, a set of them will accommodate forty-five different sizes of work. These chucks are useful for holding mainspring barrels when fitting in the cap, should it become out of true; for trueing up the barrel of English lever watches that are damaged by the breaking of a mainspring and for holding almost any wheel in a watch, such as the fitting of a center wheel to a pinion, or in making sure that hole in the wheel is in the center. These chucks will the hold wheels from 5 to 2.25. The chucks mentioned above are the most common ones in every day use and usually accompany the American lathe in combination sets. As intimated, these chucks are delicate and as a usual thing they do not receive the care they should, when their cost and the delicate exactitude demanded of them is considered. The watchmaker who prides himself on his good work and the orderly condition of his tools, attachments and bench generally will purchase or make for himself a nice chuck box with a glass or wooden cover to exclude all dust and flying chips. You cannot expect to do good true work with a chuck that is thrown carelessly into a drawer containing an assortment of files, a hammer, staking block, oilstone, screw driver, sliding tongs, etc., and yet how many watchmakers take just this kind of care of their chucks, and complain of their untruth, and declare that a wax chuck is the only thing that can be absolutely relied upon for truth. Fig. 81 illustrates a neatly arranged chuck box made by the Faneuil Watch Tool Company. In it all the various chucks may be arranged and the whole may be covered with a glass shade to keep out all dirt. A wooden cover might be used and perhaps would be preferable to many as it is less liable to be broken and occupies less space and therefore admits of the box being placed in a drawer, leaving more room on the bench for the necessary tools and attachments.

[Illustration: _Fig. 80._]

[Illustration: _Fig. 81._]

A chuck box should be well soaked in oil so that the wood will absorb no moisture and thus tend to rust the chucks. A small envelope made of tissue paper and filled with quicklime will, if placed in the chuck box, take up the moisture in the air and prevent the chucks from rusting.

[Illustration: _Fig. 82._]

=260.= The chuck stepping device, invented and patented by Mr. Moseley, is a valuable attachment for the lathe. In this device, shown in Fig. 82, _a_ rests in chuck slightly less than diameter of work; _b_ tightens in rear end of draw-in spindle, and turning _c_ regulates the depth of step. By the use of this tool any wire chuck will accurately serve as a step chuck. It is a device of great service to the watchmaker when used and understood. It enables him to make a step in any wire chuck of any depth he may desire, and will push out the work at any time when he so desires. It is very useful many times for a stop for marking or cutting off when you want a number of pieces of the same length or kind. Many object to the stepped chuck for general use.

[Illustration: _Fig. 83._]

=261.= In addition to the regular chucks which usually accompany American lathe combinations may be mentioned some others which from time to time have been placed upon the market by manufacturers of watchmakers' tools. These chucks were devised for holding work which it was found in practice could not be held by the ordinary chucks.

=262.= The bezel chuck, shown in Fig. 83, was originally made with a view of holding bezels only, but is now made so that it will hold watch plates, coins, etc., and is adjustable to any size. It can be fitted to any lathe and it requires but very little practice to use it, as it is extremely simple and any one who uses a lathe can make or repair bezels in a workmanlike manner. It holds the work as in a vise, and no amount of turning or jarring will loosen the jaws, while it may be opened or closed instantly by simply turning the milled nut behind the face plate, thus enabling the operator to turn and fit a bezel perfectly, by trying on the case as many times as necessary. It holds the bezel by either groove, so that the recess may be turned out when too shallow or too small for the glass, or the bezel may be inverted and turned down when it rests too hard against the dial. It will be found especially useful in turning out the inevitable lump of solder from the recess of the bezel after soldering, and in fitting to case, as the process of soldering generally makes the bezel shorter, and consequently it will not fit the case. It also renders the operation of polishing bezels, after soldering, the work of but a few moments. In turning out the recess for glass in bezels, especially those of the heavy nickel variety, it will prove a friend indeed. When, for instance, you look through your stock of flat glasses and find none to fit, but have one that is just too large. Any watchmaker knows that if the groove in the bezel is imperfect, it is very apt to break the glass. This chuck is also useful as a barrel closer, holding work while engraving, and many other uses that will present themselves to the watchmaker.

[Illustration: _Fig. 84._]

=263.= The Hopkins' patent adjustable chuck, shown in Fig. 84, is designed to grip and hold firmly and accurately any size of work, from the smallest staff to the largest pinion, watch wheels of all sizes, mainspring barrels and other large work, and can be adjusted to any make of lathe, by simply placing it friction tight on a plug chuck fitted properly to the lathe. In using this chuck for staffs, pinions, wire, etc., fasten a V-piece, 7, of proper size, in the hole of attachment 6, taking care that both the V and the seat in which it rests, are free from chips, dirt, etc. Then lay your work in the V and fasten it there by means of the sliding jaw above it. This done, place the attachment on the face of the chuck body, with the disc slipped under the heads of the two spring bolts, and then spin the work to center the same as when using wax. After centering thus, fasten the disc to place by tightening the nuts on the back ends of the spring bolts. For holding work by the web of the wheel, place the wheel under the screw cap, on the face attachment 8, and screw the cap down firmly on it, with the staff or pinion projecting outward through the center hole. This done, proceed the same as when using attachment 6. For mainspring barrels and like work, use attachment 11, and place a bit of broken mainspring between the work and the ends of the three binding screws, and tighten the screws down on this instead of directly on the work.

[Illustration: _Fig. 85._]

[Illustration: _Fig. 86._]

=264.= The Spickerman patent cement chuck, shown in Figs. 85 and 86, holds and centers accurately any wheel in a watch while drilling, polishing or fitting new staffs or pinions, and all danger of injuring the wheels is obviated. It will fit all kinds of American or Swiss lathes. The holder shown in Fig. 86 at _a_, is turned down to nearly the size of the screw for the lathe, and the screw is cut so the holder will set as close as possible to the lathe. The face of the holder is then turned perfectly true. Put the wheel to be centered in cap _c_, as near to the center as convenient, and then screw on _b_. Then place the cemented face of chuck _b_ against the face of holder _a_ on the lathe, and with a lamp warm the cement between the surfaces, holding the chuck by means of a pegwood against the pivot of the wheel in the cap _c_, and it will move to an exact center as soon as warmed sufficiently. New

cement should be added occasionally between the surfaces, as the old cement hardens and burns away, and does not center as well as when new. Fig. 85 shows chuck with wheel inside ready for centering and drilling.

[Illustration: _Fig. 87._]

[Illustration: _Fig. 88._]

=265.= The gem patent pivoting chuck, shown in Figs. 87 and 88, is intended as a substitute for wax when performing pivoting and like work. By the means of the ball _b_, placed between the two sliding sockets _c_, _c_, with the several other parts as represented in Fig. 87, a combination of sliding and ball and socket movements, in connection with a spring pump-center is obtained. A set of ten or more supplementary chucks _g_, with different sizes of center holes, and attachment _n_ for all sizes of wheels, are furnished with each chuck. The supplementary chuck _g_, in the form of a small split chuck, is made to fit into a hole with taper mouth, in the center of the ball _b_, and is drawn into place and the work fastened firmly in it by means of the binding nut _m_, which screws on to a projection extending outward from the front of the ball. To use this chuck, proceed as follows: Remove the nut _m_, and give freedom to the working parts by loosening the large back nut _k_. Then to bring the hole through the ball _b_ into line, spin the ball to center, first at the base of the projecting screw and then at the mouth of the hole through it, and in this position again fasten the parts, by tightening the nut _k_. Then give freedom to the pump-center by slightly loosening the set screw _j_. When doing this, hold your finger against the front of the chuck, to prevent the center rod from shooting out of its place when freed. Then having placed a supplementary chuck _g_, of proper size, in its place in the chuck, and your work in it, with its back end resting properly in the countersink in the end of the pump-center, fasten it there by screwing the cap _m_ down snugly over it, using a small lever pin when necessary for the purpose, but not with undue force. Then again loosen the nut _k_, and spin the work to center at its outer end; and then tighten both the nut _k_ and set screw _j_. In tightening the set screw _j_, make sure it is so tightened as to prevent the pump-center from slipping from place when working. If from tightening the screw _j_, it is found that the work has been thrown in any degree away from true center, loosen the nut _k_, leaving the pump-center fast, and again spin to center and fasten as before. After a little practice this can all be done in a few seconds, and the work brought to absolute center.

In using attachment _n_, for wheels, the nut _m_ and chuck _g_ are removed, and n is substituted therefor; the work being held on the face of the attachment by flat-headed screws that grip the arms of the wheel. For cylinder escape wheels a special attachment _n_ is furnished.

[Illustration: _Fig. 89._]

[Illustration: _Fig. 90._]

=266.= Fig. 89 illustrates a crown chuck, which is used for holding crowns while undergoing repairs. The Dale chuck shown in Fig. 89 is made on the lines of the ordinary split wire chuck, a large recess being turned in the end for the reception of the crown. The Johanson chuck is illustrated in Fig. 90, and is quite different in construction, a ball-shaped cap with right hand thread screwing down onto the body of the chuck, thus holding the crown from the outside, while a screw-center with left hand thread, holds it firmly from the inside. This chuck is made in two patterns, one for use in a No. 40 wire chuck, as shown in Fig. 90, and the other is mounted on a regular chuck and is ready to insert into the lathe-head the same as an ordinary wire chuck.

THE SLIDE REST.

[Illustration: _Fig. 91._]

=267.= The slide rest is an expensive but very useful adjunct to the lathe. It is used so extensively in this country, however, that a full description of it seems superfluous. Fig. 91 is a fair example of a modern slide rest for the American lathe. The tool-holder varies with the different makers, but the rests proper are all made on the same general principles, that of two sliding beds working at right angles to each other, and carrying a tool-holder, capable of being raised or lowered or set at any desired angle.

=268.= Brass is easily turned with the slide-rest in an ordinary lathe arranged for the purpose, but the turning of steel demands more care in setting the cutter so as to obtain the best cutting edge as well as in determining the point of application of the tool. Preliminary trials must be made, and the following remarks will be of service as a guide.

[Illustration: _Fig. 92._]

=269.= Engineers use a hooked tool to a very great extent for both planing and turning. Both experience and reasoning point to the conclusion that a tool of the form _b_ or _d_ Fig. 92, possesses many recommendations, and numerous designs of hooked tools more or less resembling these figures are employed with advantage; the tool occupies the best possible position in reference to the surface it is required to cut, and the cutting edge is both sharp and solid. It will be evident that a certain relation exists between the cutting angle and the point of application of the tool to the cylindrical object that is being turned, and this it is necessary to determine. With a hooked tool, as with the ordinary slide-rest cutter, a cutting angle which is too acute will wear away rapidly; when too obtuse, the tool scrapes and will only act when considerable pressure is applied.

In conclusion, it is clear that in forming or re-grinding any tool for cutting a surface, it must be so arranged that its edge makes the least possible angle with the surface that is consistent with the securing of a sufficient degree of resistance to the cohesion and the hardness of metal operated upon; in other words, the end of the tool must be almost tangential to the circumference of the object, and the angle of the cutting edge must be obtained by removing metal from the top face of the tool. These principles are applicable to all tools for metals; to the blades of drills as well as to the cutting edges of gravers, etc.

=270.= The angle of the cutting edge of the tool used in the slide rest for steel should be less than that employed for operating on brass. According to Holtzapffel, it may vary in the former case from 60° to 80° and, in the latter case, 70° to 90°, according as the tool is required for rough turning or finishing. 60° and 80° may, however, be taken as convenient angles in the cases respectively. Simple methods of ensuring that the cutting edge has any required angle are described in article 396.

The velocity with which the lathe revolves should also be less when turning steel, and care must be taken that both the tool and object are constantly moistened with oil.

It is sometimes desirable to arrange a small dropping-can for the purpose of keeping up the supply; this may be easily done by placing a can containing the fluid above the level of the work and allowing a piece of lamp-wick, previously moistened, to hang from it so as to almost touch the work: a continuous series of drops will fall, owing to the influence of capillarity.

[Illustration: _Fig. 93._]

=271.= When roughing out work it is best that the cutter first travel perpendicular to the object, from _a_ towards _b_, Fig. 93, and then in the direction of the arrow. The corner _a_ should only be used for finishing an internal angle or for roughing it out, and, in this latter case, the cutter must advance along _a b_ and be withdrawn from the metal in the direction of the arrow. The small face at the end, _a c_, should be narrow.

[Illustration: _Fig. 94._]

=272.= =Forms of slide-rest cutters.= The usual forms of cutters for use in the slide-rest are shown in Figs. 94 and 95. A and A′ are respectively the plan and side view of the most common form. Two inclined planes _i n_ and _d c_ are formed on the left-hand and under sides. The point on which they terminate is cut off square, a cutting edge, which is more or less acute according to the metal to be operated upon, being obtained by a third incline _c n_. The width of the square cutting edge, indicated at _n_ in figure A, varies according to the metal to be operated upon, as well as this incline _c n_. It is advisable to be provided with at least half-a-dozen cutters of this form, with edges of varying width and inclination, and even this number is often found insufficient; cutters for steel should never be used in turning brass.

[Illustration: _Fig. 95._]

A cutter may be sharpened in the usual manner for ordinary work; but if it is desired to produce very smooth sinks, etc., one that has been carefully polished must be used for the final cut.

The blade should cut with both its edges; the straight edge will serve to form right-angled corners of sinks, while the other edge will form bevels. It is hardly necessary to add that, when a square corner formed by the first of these edges requires to be beveled by the second, the lathe must rotate in the opposite direction and the cutter be passed over to the opposite side of the center.

=273.= C, in the same figure, is a rounded cutter for making circular grooves. F, Fig. 95, is for cutting the groove that receives a barrel-cover. J and V are for forming the “tallow-drop” shoulders of pivot-holes, etc.

It will doubtless be observed that these cutters would form nipples that are dome-shaped and relatively somewhat high, and, for small pivot-holes, the blade would require to be narrower and of a shape that corresponds with the nipple it is desired to produce. L is for rounding off angles. S is a convenient shape for smoothing the bottom of a barrel without damage to the hook. T has a square point; it is used narrow for cutting, for example, the passage under the escape-wheel cock in a cylinder watch, and, when made wider, will serve to cut the settings for jewels. In the latter case it may either be square at the end or a little rounded at the corners.

In addition to the use indicated above, V can be employed for raising the edge of a jewel setting.

=274.= =Sharpening slide-rest tools.= A flat surface turned in the lathe will never be even unless the cutting face _n_ in A Fig. 94, is smooth, and indeed polished, and its edge parallel to the face-plate. Some care is therefore necessary in sharpening this face. The requisite parallelism can be secured by the following method.

=275.= Sharpen the tool while it is held in the tool represented in Fig. 96.

[Illustration: _Fig. 96._]

On a thick brass plate _l_ and parallel to its plane at one extremity _b_, a plate _p_ is pivoted. The inclination of _p_ to _l_ can be varied and it is fixed in any required position by the curved arc passing under the clamping screw _j_.

A small bar _c_ is fixed to _l_ with its edge set accurately at right angles to the line at _b′_ in which the two planes intersect. An examination of the figure will suffice to indicate the manner in which such a tool is used. Having set _p_ so that it makes with _l_ the angle to be given to the cutting face, the cutter _b_ is held against the bar _c_, where it may be fixed with a screw _v_, or in any convenient manner, taking care to leave the portion of the cutter that is to be removed projecting beyond the face of _p_ as shown at _b′_. Now pass a piece of smooth oilstone or disc of steel charged with oilstone dust over the face of _p_ until the projecting portion is removed; if a polished face is required, this must be succeeded by a bronze or ground glass disc charged with rouge. If the plate _p_ is of sufficient dimensions, it will not be distorted, even though only made of hammered brass; but it would of course be better made of steel, hardened if possible.

=276.= If the watchmaker will make a rectangular holder to fit in his tool post, with a square groove planed in its upper side that will fit some particular size of tool steel, say one-fourth or three-sixteenths of an inch, he can then buy bar steel of that size and make his cutters by simply cutting off a piece from the bar and grinding one end to the desired shapes and angles, thus saving a vast amount of time and labor in the preparation of his tools, facilitating their rapid interchange in the tool post, when working, and securing the greatest possible rigidity of the tool, as the cutting edge projects from the holder only far enough to allow the holder to clear the work.

GRAVERS AND OTHER HAND-TURNING TOOLS.

=277.= =Hooked gravers.= It is needless to do more than mention the gravers that some watchmakers are in the habit of making of worn-out files, of various forms to suit their special requirements; but we would remind learners that care is essential in fixing the position of the rest and the inclination that has to be given to the tool so as to obtain a smooth surface, and at the same time a rapid removal of metal.

The most usual forms of the hooked graver are shown in Fig. 97. A will serve to hollow out a plate, barrel, etc.; B for turning the bottom of a barrel without touching the hook; C for forming a barrel-cover groove after it has been roughed out with an ordinary graver. The bottom of a barrel can also be turned with a graver of the form D held on the =T=-rest at right angles to the bottom, and a slide-rest cutter can be made of this form with advantage.

[Illustration: _Fig. 97._]

Some workmen incline the end cutting face of A slightly backwards from the perpendicular to _d d_, fearing lest, in sharpening, it should accidentally be made to incline in the other direction, and so make it difficult to form internal square corners.

=278.= =Gravers for turning square shoulders, etc.= Very few watchmakers are able to finish off a square shoulder by using a graver with the usual point; as a rule, when they are smoothing the surface of the pivot they allow the point to cut a ring in the shoulder, and if, instead of being sharp, the point is dull, a rough groove is the result.

To avoid such a fault it is a common practice to employ gravers with very short faces, but their inconvenience is evident. It is much better to retain the long lozenge-shaped face, but with the point modified, as indicated by B or C, Fig. 98.

The ordinary point, shown at A, can be used for cutting the back slope of a shoulder, B for forming the square-shouldered pivot, and C for beveled shoulders. The inclination of the face _e d_ of B may vary, the angle _e_ being more or less acute, according as more or less use is required to be made of the point. This form of graver has the double advantage that a pivot can be turned and smoothed at one operation, very little polishing being needed. Moreover, the point is less fragile, and such a graver combines the advantages of those with pointed and square ends.

[Illustration: _Fig. 98._]

The length of this small face depends on the work required of it, thus for making a cylinder pivot it may be about a third the length of the pivot; this is found convenient for ensuring that the pivot shall be of uniform diameter. The direction to be given to the face is indicated by the dotted line _e d_, and a lozenge-shaped graver is preferable to one of square section for this purpose. This direction _e d_ is very important, and frequent trials should be made so as to ensure its being always produced. The form C for beveling off a shoulder does not call for explanation.

Although of less importance than when turning with the slide-rest, the cutting angle of the graver should correspond with the nature of the metal operated on. In reference to this question see article =270=.

=279.= =Spherical turning tool.= A very simple and convenient tool for forming a sphere of metal may be made by taking a hardened steel tube whose internal diameter is less than that of the sphere to be produced. This is ground square and flat at one end, and sharpened by rubbing this flat end on an oilstone. The tool is moved about over the surface of the ball, previously roughed out, and a perfect sphere will soon be obtained, the metal being removed by the internal edge of the tube. If a steel tube is not accessible it will be enough to drill a hole in the end of a softened worn-out file, subsequently hardening it.

DRILLS.

[Illustration: _Fig. 99._]

=280.= The forms ordinarily adopted for the blades of drills are shows at A and C, Fig. 99. The form C is best suited for perforating brass and other metals having a similar degree of hardness. The blade must not be too thick, as, if it were, there would not be a sufficient cutting edge. As the hardness of the metal operated on is greater, the thickness of the blade must proportionately increase, or what amounts to the same, the two slopes that give the cutting edges must have a less degree of inclination. If this condition of sufficient thickness be satisfied by a drill of the form C, it will perforate steel very well, but its point will rapidly wear. When operating on this metal, therefore, the form A is preferable, especially when the steel is at all hard. Such a drill with the corners rounded off and sharpened will last for a long time, if the cutting angles are not too acute. If the metal is not hard, more rapid progress may be made by adopting a blade less flattened than A, that is to say, something intermediate between A and C.

A drill may be asserted to be good if it satisfies the following conditions: the point must be in the middle of the blade; it must be made of good steel that is carefully hardened, without being heated beyond the proper temperature; lastly, it must be quite true—in other words, in rotating it must run with sufficient truth throughout its entire length, so that it withstands the end pressure required to cause it to bite, and does not bend.

=281.= It must not be forgotten that: (1) if a drill is driven too rapidly it will heat, and thus become softened as though too much tempered; it is with a view to prevent this that, when operating upon iron or steel, many workmen now and then dip the drill into a cold liquid (turpentine is good for this purpose), dry it, and recommence drilling, the hole being liberally supplied with oil; (2) when the blade is left too hard, the cutting edge too acute, or if a feather edge has been left by the oilstone, small hard particles that are detached from the drill will embed themselves in the hole, and this will be especially the case if it is worked too rapidly or with jerks; such particles render the operation of drilling very slow and difficult.

=282.= =To drill steel of a blue temper.= At first not much difficulty will be experienced; but when the drill reaches a certain depth and the metal seems to oppose a gradually increasing resistance, the operation must at once be stopped. If the blade of the drill be now examined with a glass, it will be easy to see which points have ceased to cut, producing instead a series of bright rings at the bottom of the hole that are very difficult to remove. Exchange the drill for one of a different form or, without reducing its width,

change the form of the blade; if it was arrow-headed for example, make it a semicircle, or semi-oval, or chisel-shaped with sloping edges. All that is essential is that the form be so changed that the bright portions of the surface shall be gradually removed, and that no attempt be made to act on the whole bright surface at once. Until this hard portion is removed, the blade will require frequent sharpening.

Some authorities recommend that the hole be moistened from time to time with dilute nitric acid, which is then washed off, and renewed when a shiny surface is produced. Oil can with advantage be replaced by turpentine as a lubricant for the drill blade.

The formation of hard shining surfaces is attributed to three causes: (1) to the cutting edge being rounded, rolling as it were and hardening the surface of the metal against which it continues to move; (2) to the drill being made of bad steel or imperfectly hardened, so that small particles break off and are embedded in the metal operated upon; and (3) to a deficiency in the supply of oil, or an excessive velocity of rotation of the drill.

These difficulties may usually be avoided by observing the following precautions:

[Illustration: _Fig. 100._]

=283.= _Blade of the drill._ This should be neither as thin nor as acute as is used for drilling brass. Its angle should never be less than 100° and the incline should be at about 45°. The forms generally employed are shown in Fig. 100, at A, B and C. At first the form A is used, and, as the operation progresses, it is modified with an oilstone slip.

=284.= _Drilling slowly with considerable pressure._ If the drill rotates too rapidly or there is not sufficient oil, the surfaces of contact will be heated and shining rings will form. It is well to practice slightly, varying the speed of the wheel, in accordance with the pressure applied; the speed should be more decided when the pressure is, for the instant comparatively great. With continuous rotation, considerable pressure should be applied with moderate velocity. Constantly remove the drill to sharpen, clean the hole and have an abundant supply of oil. Whatever liquid is most effective in maintaining the drill cool will probably be the best; turpentine is better than oil, since it has the additional advantage of increasing the “bite” of the drill.

=285.= _The part against which the drill acts should be very rigid._ For example, if a hole is being made for a pivot in a cylinder plug which is not provided with a shellac backing, and is, therefore, flexible, the operation will be more tedious than when the cylinder is filled with shellac. The firmness is usually greater when the object is centered about the point to which the drill is applied.

=286.= _Making the drill._ The very best steel should be used, and the precautions indicated in article =87= should be taken in the hardening. If the steel is burnt in this process, no satisfactory results are to be expected of it. To avoid such a danger it is often advisable to leave the blade nearly round and thicker than is required, finishing with a piece of oilstone. Although somewhat more tedious, this method has the advantage of ensuring that, after hardening, all the metal that is most liable to have been burnt is removed.

The drill must be short, the blade being thick and not much reduced at the shoulder, in order to stand pressure when in use. A drill that has been several times hardened is rarely good.

=287.= =Finished drills.= We would here draw the attention of watchmakers to some beautifully made drills that have been introduced and are known in the trade as “finished” drills, in contra-distinction to the well known pivot drills that are always sold in the rough. They are of two forms, corresponding to A and C, Fig. 99, for steel and brass respectively; they are made of the best steel, carefully hardened and tempered to the requisite degree; and a principal recommendation consists in the fact that, while being moderate in price, they are of definite graduated sizes, extending from 0.1 mm. to 2.5 mm. (0.004 to 0.1 inch), a range which comprises 37 distinct sizes.

=288.= =Semi-cylindrical drills.= These drills give excellent results when driven by a wheel, and, although they have been long in use by engineers, they are hardly known to watchmakers.

[Illustration: _Fig. 101._]

The simplest form is a cylindrical rod rounded at its end and then filed down to a trifle less than half its thickness, as seen at _b d_ and _l i_, Fig. 101.

The length of the point is greater or less according to the nature of the metal to be operated upon, but under no circumstances must the point itself be sharp. With the form shown at _b d_, some of the rod that is left cylindrical must be partially filed away; a better shape is indicated by the dotted lines, all the metal being removed that is outside the line _i l_. With such a drill the hole is smoothed immediately after it is made by one or the other cutting edge of the portion _i l_. It should be sharpened on the round, not on the flat surface (or at any rate very slightly), because the thickness would be rapidly reduced and the blade made smaller. When such a drill does not turn true the back of the blade can be reduced, starting from the cutting edge, it being observed that, with the continuous motion of the wheel, only one edge acts. After a few trials it will be found easy to use this form of drill.

It possesses this very great advantage: when fixed in a drill-chuck, it can be turned exactly round, of the required diameter and finished; so that, whenever replaced in the chuck, one can be certain beforehand that the hole drilled will be of a definite diameter.

[Illustration: _Fig. 102._]

=289.= Fig. 102, shows, at C and D, another form of semi-cylindrical drill; the first, C, is a front and the second a side view. The angle _a_ is formed by a sloping semicircle and the stem of the drill is of less diameter than the head, as indicated by the shoulder _j_. The angle _t s r_ and the one between the face D and the plane _b a_ must not be too acute.

This drill works evenly, but two conditions must be satisfied; it must be maintained perfectly true by the chuck, and, in commencing, both sides of the blade must engage against the sides of a conical opening that forms the beginning of a hole which has to be enlarged.

[Illustration: _Fig. 103._]

=290.= At F and N M, Fig. 103, are seen front and side views of another form of drill. While acting in a similar manner to the others described above, it differs from them in that the blade also cuts with its two sides; the edges, _p_, _i_, _i_, _o_, are sloped off backwards to form cutting angles. The shape is indicated to the right of M, this portion being the exact inverse of the side N.

As with the drills previously considered, a few trials must be made to decide upon the best slopes for the cutting angles, etc., according to the metal operated upon. They may be retained as left by the lathe, or very slightly inclined, on the faces _p_ and _i_. All these forms of drills require to be mounted so as to run very true. The point _o_ must be accurately central. A hole that has been already drilled small can be rapidly enlarged by such a drill as this last, the pin _o_, having the same diameter as the one originally drilled.

[Illustration: _Fig. 104._]

=291.= =The Twist Drill.= The Morse twist drill, shown in Fig. 104, is rapidly coming into favor with watchmakers for the heavier classes of work, and is very desirable when drilling deeply, as this form of drill heats slowly and the particles are carried to the surface of the work. A large range of sizes in these drills are now carried in stock by the material dealers.

LATHE ATTACHMENTS.

=292.= =Tailstocks.= Besides the regular tailstock which accompanies the American lathe there are several other varieties made for use on special kinds of work. Fig. 105 illustrates the half open tailstock which is cut away so that the spindles can be laid in, instead of being passed through the holes. The fixture will be found exceedingly convenient when several spindles are to be used for drilling, counterboring and chamfering. Fig. 106 illustrates the screw tailstock, an attachment which is very convenient for all kinds of heavy drilling, the spindle being moved by a screw with hand-wheel attached. Fig. 107 illustrates the traverse spindle tailstock, which will be found very convenient for straight drilling and especially where the watchmaker has considerable drilling to do.

[Illustration: _Fig. 105._]

[Illustration: _Fig. 106._]

[Illustration: _Fig. 107._]

[Illustration: _Fig. 108._]

=293.= =Jeweling Caliper Rest.= Although this tool was invented and manufactured for the purpose of cutting jewel settings it may be used to great advantage in countersinking for screw heads, opening wheels for pinions or bushings, etc. The sliding jaws of the calipers should be so adjusted that when the swinging part is brought back snugly against them, the front cutting edge of the cutter in the sliding spindle will exactly line with the center of the lathe spindle. Then if the calipers are at the right height, when a jewel or jewel setting is placed in the jaws of the caliper it will move the edge of the cutter outward from the lathe center just half the diameter of the jewel then in the caliper and the cutting made at that distance from the center will exactly coincide with the size of the jewel to be set. If however, when set and worked as above, it is found that the hole cut is too large for the jewel, it will indicate that the calipers are too low down and should be raised, provision for which is made in the construction of the tool. Upon the other hand, if the cutting is found too small to fit, it will indicate the calipers should be lowered. The final cutting for the jewel seat should be made by running the center straight inward from the face of the plate; the adjustable stop screw on the back end of the sliding spindle, serving to gauge the depth of the cutting.

[Illustration: _Fig. 109._]

[Illustration: _Fig. 110._]

[Illustration: _Fig. 111._]

[Illustration: _Fig. 112._]

=294.= =Pivot Polishers.= The pivot polisher is used for grinding and polishing conical and straight pivots and shoulders. It is also used for drilling, polishing or snailing steel wheels, milling out odd places in plate or bridge, where only a part of a circle is to be removed, etc. In the style shown in Fig. 109, the American Watch Tool Co.'s polisher, and Fig. 110, the Moseley pattern, the circular base is graduated to degrees and the fixture can be set at any angle. The spindle has a taper hole for drill chucks, which makes the fixture very useful for drilling either in the center or eccentric and by using the graduations on the pulley of the headstock an accurately spaced circle of holes may be drilled. Fig. 111 illustrates the polisher made by the Faneuil Watch Tool Company, and is intended to be mounted on the slide rest. Fig. 112 illustrates the Johanson pivot polisher and in general principle is like the others. This style is made both for use on the slide rest and also for the hand rest. When used in the latter, a stud, shown in Fig. 113, is screwed into the base plate and supports the tool in the hand rest, so as to be readily adjustable in any direction. When used in the slide rest, this stud is removed and the plate clamped between two hollow cylindrical supports by a stud which is slipped into the groove of the slide rest and fasted by a nut at the top, the whole forming a turret-like mount of great strength and upon which the machine can be readily swiveled in any direction. In general, polishers are used as follows: After the pivot is turned to proper shape, put on your polisher, with the lap back of the pivot, usually the cast iron lap first. A square-cornered lap for square shoulders and a round-cornered lap for conical pivots. The laps for conical pivots can be readily cornered with a fine file, and cross-ground with fine oilstone to remove any lines made by graver or files. Lines on the end can be removed the same way, or by means of the fingers often rubbing them on a piece of ground glass which has on it a paste of oilstone powder and oil, well mixed. Oilstone powder and oil used on the lap, or No. 1 crocus will rough out the work well. When roughed out to your liking, wipe off the oilstone powder or crocus and with a little oil touch the pivot gently; repeat the second time. Then change lap for one of boxwood or brass and use crocus No. 4, very fine, and ground down to a paste. Proceed as with the first lap, being careful at all times to keep the lap properly oiled and not pressed too hard against the work, particularly in the last operation. Be sparing of your grinding and polishing material as a little will accomplish as much work as a large quantity and do it better. Bring the lap up carefully against the work until spread all the way around, then proceed, bearing in mind that grinding is not polishing, and that to polish nicely the work and lap must be very nearly the same shape. Fig. 114 illustrates the Hardinge pivot polisher, which is a hand polisher and much more simple in construction and use than those mentioned above. It is attached to the lathe bed the same as the T or hand rest. Polishing and grinding slips are furnished with this attachment, as with the others.

[Illustration: _Fig. 113._]

[Illustration: _Fig. 114._]

=295.= =Centering Attachments or Back Rests.= These attachments are very useful in rapidly bringing work to an accurate center, when pivoting, staffing, etc., and particularly where a large number of pieces have to be centered successively. Fig. 115 illustrates the Potter patent self-centering lathe attachment which is made to fit any pattern of American lathe.

[Illustration: _Fig. 115._]

It consists principally of the slide bed pieces _R_ and _D_, the upright plate _A_ and the reversible anti-friction sliding jaws _O U V X_. The upright plate _A_ is attached to the slide _D_ in such a way that it may be readily raised or lowered, or adjusted in any other direction at pleasure; and may be set with either side facing the lathe-head. The sliding jaws are made of phosphor bronze anti-friction metal and four sets, of three in a set, are furnished with each attachment, as shown at _O_, _U_, _V_, _X_, the forms differing so they may be adapted to the various kinds of watch work, and they are operated in radial grooves in the upright plate _A_ by means of the rotating lever _L_, which moves the three jaws in and out, to and from the center, or opens and closes them in perfect unison. One set of jaws may be withdrawn and another set substituted therefor in a few moments. With each change of the jaws, however, the plate _A_ requires readjustment, but this too, may be done in a few moments, as follows: Having previously provided yourself with a bit of straight wire or a small steel rod, turned to run perfectly true in your lathe, and having fastened this in your chuck in the lathe, loosen the nuts _C C_, so as to give freedom of movement to the plate _A_; then bring the attachment to proper position on the lathe bed and fasten it there, after which move the sliding jaws inward until they bind tightly on the piece of straight wire held in the chuck and in this position again tighten the nuts _C_ _C_. Once adjusted to accurate center in this way, no further adjustment, whatever the size of the work to be operated upon, is required, until you make another change of jaws.

In use, the end of the work to be operated upon is placed in an accurate split chuck in the lathe, and the chuck tightened on it, just sufficiently to hold it in place and to rotate it, the other end being supported in the central bearing, formed by the sliding jaws. In this position the jaws may be opened or closed as often as desired, and each time they will bring the work to accurate center.

A similar attachment to the one above described is extensively used by machinists and is known as the back rest. In principle it is very similar, but is more simple in construction, and ambitious workmen can make them without difficulty. This attachment, which is shown in Fig. 116, differs in its mode of fastening to the lathe bed and the jaws cannot be opened and closed at one time as in the Potter attachment.

[Illustration: _Fig. 116._]

The illustration shows the rest in position on the lathe bed, looking from the right-hand end of bed; _m_ shows the base, looking from above, in direction of arrow _k_; _d_ shows bolt for binding it to the lathe bed. It does not seem as though it needed much explanation, as it will be readily seen that the head _d_ of bolt, passes up through the longitudinal slot in the lathe bed, through the round hole in base of back rest and is slipped back into slot _m_, when about half a turn of nut _g_ binds it firmly to the bed. The washer _h_, on the end of the binding screw, is riveted or soldered in place and should be close enough to nut _g_ to allow only about half a turn to loosen the bolt, as that is sufficient, and more space would occasion a loss of time in running the nut back and forth to bind or loosen the rest. It will be seen that when the nut _g_ is slackened, it binds against the washer _h_, and it will stay there, and be just where you want it when you are ready to use it again. The jaws are of hard brass; about three sets, with points of different widths, will cover a large range of work. Those shown in Fig. 116 are suitable for such work as pivoting small French clock pinions, etc. It will be observed that the jaws are so made that they may be changed by slightly loosening the screws. The screw heads should have thin steel washers under them.

[Illustration: _Fig. 117._]

[Illustration: _Fig. 118._]

=296.= =Universal Head.= The universal head has entirely superseded the clumsy universal mandrel in this country. The example shown in Fig. 117 is more accurate, less clumsy and complicated and will perform all the work that can be performed on the universal mandrel. The face-plate is 3½ inches in diameter, but by the use of the two crescent-shaped slots it will hold anything in size and shape of watch work. The pump center is operated from the back by the rubber knob and can be used either with or without a spring. The jaws, which will pass the center, are held in position on face of plate by springs and are fastened from the back. Peep holes are provided in these heads in order that the workman may examine the back of the work at all times. In the Moseley head, shown in Fig. 117, these holes are of taper form. Fig. 118 shows a universal face-plate to be used in a chuck in the lathe. It is smaller and less expensive than the universal head and answers very well for some work, especially that of the lighter kind, but cannot be recommended as highly as the universal head, as it is not so accurate. The pump center is used to center, from the back, any object confined in the jaws, but it sometimes becomes necessary to mount the object, by means of wax, upon a plate, and hold the plate in the jaws. In such a case the work must necessarily be centered from the front. This can be done accurately by means of a piece of pegwood, as ordinarily done on the lathe, by placing the point in the center hole and the pegwood resting on the T-rest and observing if the free end of the pegwood remains stationary.

=297.= =Traverse Spindle Grinder.= This tool will be found very useful for grinding cutters, lathe centers, pump centers, reamers, countersinks, squaring up barrel arbors after hardening, or work on any hardened steel tool. In the hands of an ingenious workman, it will be found exceedingly useful, as by its aid a great variety of work can be performed that cannot be accomplished without it. Fig. 119 is intended to be attached to the slide rest.

[Illustration: _Fig. 119._]

[Illustration: _Fig. 120._]

=298.= =Milling Fixture.= This attachment, which is shown in Fig. 120 is designed to be fitted to the slide rest and holds the wire chuck vertically under the center of the lathe, so that articles held in the chucks can be fed under mills or saws held in the saw arbor in the lathe-head.

[Illustration: _Fig. 121._]

=299.= =Wheel Cutters.= The wheel cutter is a valuable addition to the lathe. Several different styles of these attachments are made, each possessing points of merit. They are designed for cutting all kinds of wheels and pinions used in key and stem-wind watches. When the cutter spindle is vertical the belt runs directly to it from the countershaft, but when horizontal, the belt passes over idler pulleys held above the lathe. One style of wheel-cutting attachment is shown in Fig. 121, while another style is shown in Fig. 71.

[Illustration: _Fig. 122._]

=300.= =Rounding-up Attachment.= The Webster rounding up attachment, shown in Fig. 122, is a very useful adjunct to the lathe. It is attached to the top of the slide-rest. To operate, a pointed taper chuck is put in the lathe spindle. The wheel to be rounded up is put into the fixture and the wheel adjusted vertically so that the point of the lathe center will be at the center of the thickness of the wheel, after which the lower spindle of the fixture should not be moved. Now remove the wheel, also the taper chuck, and put the saw arbor, with the rounding-up center, in the lathe spindle, and adjust the longitudinal slide of the slide-rest so that the rounding-up cutter will be back of and in line with the center of the rounding-up fixture, after which the longitudinal slide of the slide-rest should not be moved. Now put the wheel and supporting collet in place, and proceed with the rounding-up.

MISCELLANEOUS SMALL TOOLS.

[Illustration: _Fig. 123._]

=301.= =Screw Head Sink Cutter.= This is usually made in the form of an arbor terminating in a cutting edge similar to the rose-cutter, but having a projecting pin from its center. This tool will be found especially useful in replacing broken end-stones. The jewel being set in brass, is held by two screws, on opposite sides, the screw heads being let in or sunk even with the surface, half of the screw head projecting over on the end-stone. The end-stones furnished by the watch companies are not sunk for these screw heads, but are round and of the proper diameter. These cutters will cut away from the jewel setting the space to be occupied by the screw head in a very few moments and in a very perfect manner. All of the watch companies do not use the same diameter of screw head in the cock and potance, consequently you will be compelled to make separate tools for the different makes of watches. With a set of five or six of these cutters you can fit any American watch. After you have completed your set, of say five or six cutters, select a small brass plate and bore five or six small holes in a row, in which the guide pins of the cutters will enter, and then cut with the tools a number of sinks, numbering these holes in the plate and also the arbors of the tools with corresponding numbers. You will then have a plate similar to Fig. 123 which can then be used as a gauge for measuring the heads of screws.

[Illustration: _Fig. 124._]

These cutters are easily made as follows: cut off a piece of wire of the required diameter, about one inch long, and place it in a chuck that fits it snugly and turn one end to a center, about 40°; now reverse the wire in the chuck and be sure it is true; select a drill that will pass through the screw hole in the cock or potance freely and proceed to drill a hole in the center of the end of the wire, about ½■■ of an inch deep. Remove from the lathe and with a sharp file and graver, proceed to cut a series of teeth as equal and even as possible. Use a good strong glass while working and be sure you have every tooth sharp and perfect, as upon this depends the quick and nice work you expect from the tool. When this is well done, proceed to temper fairly hard and polish up the

outside to make it look workmanlike. Now select a piece of steel pivot wire, of a size that will almost fit in the hole drilled in the end of the tool and polish down to the proper size to drive in the hole tightly. Allow the wire to project about ½■■ of an inch, taper the point and polish. The tool is now complete and will resemble Fig. 124. Select an end-stone of a diameter to fit tightly in the cock or potance, as maybe required; set the hole jewel in place and then the end-stone pressed down tightly against the hole jewel. Place your cutter in a chuck that fits it true; select a smaller medium sized drill rest and place it in the tail stock spindle. Hold the cock, or potance, with the jewels in place, against the drill rest, level, and proceeding to run the lathe at a fair speed, slowly feed the cock or potance to the cutter, the projecting pivot in the end of the cutter passing through the screw hole and acting as a guide to keep the cutter in the center of the hole. Caution must be exercised, or you will cut the recess for the screw heads too deep, as these little cutters are very deceiving and cut much faster than you would suppose. In fitting an end-stone, select one that is more than flush when the jewel hole and end-stone are in the proper position, and after sinking the screw head as described, turn off on the lathe almost flush or level. Make a small dot on one side of the end-stone as a mark or guide in replacing it. Remove the end-stone and proceed to polish the top of the setting on a plate glass polisher.

=302.= =Screw Extractors.= The Bullock Screw Extractor, shown in Fig. 125, is a simple yet very valuable tool to the watchmaker who finds he has a plate in which a screw has been broken off. To use this tool, first fasten it in your vise, then bring one end of the broken or rusted-in screw against screw center and the broken screw head against screw driver; turn the washers so as to hold the broken screw firmly in place; turn the plate gently and the broken screw will follow the screw driver point out of the plate. It may be necessary in some instances to turn the screw driver point against the broken head with a good deal of force in order to start the screw. A little benzine or kerosene applied to the screw will help to loosen it.

[Illustration: _Fig. 125._]

The ingenious workman can, with the expenditure of a little time, make an attachment for removing broken screws, somewhat similar to the above. Take two common steel watch keys having hardened and tempered pipes—size, four or five—having care that the squares in each are of the same size and of good depth. Cut off the pipes about half an inch from the end; file up one of these for about one-half its length, on three equal sides, to fit one of the large split chucks of the lathe. Drill a hole in one of the brass centers of the lathe of sufficient size and depth, into which insert the other key-pipe, and fasten with a little solder. Soften a piece of Stubbs' wire, to work easily in the lathe, and turn down for an eighth of an inch from the end to a size a little smaller than the broken screw in the plate; finish with a conical shoulder, for greater strength, and cross-file the end with a fine slot or knife-edge file, that the tool may not slip on the end of the broken screw; cut off the wire a half inch from the end and file down to a square that will fit closely in one of the key-pipes. Make a second point like the first one and fit it to the other key-pipe; harden in oil, polish, and temper to a dark straw color. Fit the brass center into the tail stock. To use, put the tools in place in the lathe, place the broken end of the screw against the end of the point in the lathe-head; slide up the back center and fasten the point firmly against the other end of the screw, that it may not slip or turn; revolve the plate slowly, and the broken screw, being held fast between the two points will be quickly removed. To remove a broken pillar screw, place the broken screw against the point in the lathe-head, holding the plate firmly with the right-hand, the pillar on a line with the lathe center; turn the lathe-head slowly backward with the left-hand, and the screw will be removed. Should the tool slip on the broken screw, and fail to draw it out, drill a hole in the lower or dial side of pillar, down to the screw point (if the size of the pillar will admit of it), and with the second point in the back center, remove the screw in the same manner as in the first process. Five or six sizes of these points will be found sufficient for the majority of these breakages that may occur.

It sometimes happens that a screw gets broken off in a watch plate in such a manner that it is impossible to remove it with tools without marring the plate. In such an event proceed as follows: Put enough rain water in a glass tumbler to thoroughly cover the plate and add sulphuric acid, until the water tastes a little sharp. Place the plate in the solution and allow it to remain a few hours, when the screw will partially dissolve and drop out. Remove from the solution, wash thoroughly in clean water, then in alcohol and dry in saw dust. The solution will not injure the brass plate or gilding in the slightest, but care must be taken to remove all other screws or cemented jewels, previous to immersion.

[Illustration: _Fig. 126._]

=303.= =Roller Remover.= There are numerous designs in the way of roller removers upon the market, some of them good but many of them weak and liable to bend where the roller is very tight on the staff. All points being considered, the Hardinge remover, shown in Fig. 126, is perhaps the strongest and best on the market and is built on true mechanical principles.

The nose in the center and top of the illustration is drilled up so as to receive a balance pivot without bearing on its point, and can be moved towards or from the two bent prongs by means of the thumb nut at the bottom of the tool. The prongs can be spread apart or drawn together, and are secured in place by means of the binding screws at the sides. In using the remover the feet of the two prongs are brought under the roller and secured by the binding screws. The nose is now advanced against the shoulder of the bottom pivot and the staff can be driven out without damage to either roller or staff.

[Illustration: _Fig. 127._]

=304.= =Balance Protectors.= These are of two kinds and for entirely different operations. The Arrick protector, shown in Fig. 127, is used for protecting balances while working upon the pivots while in the lathe. No matter how careful a person may be, accidents will happen, and the least accident to a compensation balance gives the workman considerable trouble. The least slip of the graver, polisher or hand rest and great damage is the result. The staff is passed through the hole in the protector, and held in a wire chuck, and the protector is secured to the arms of the balance by two screws. The Bullock protector, shown in Fig. 128, is designed to protect the balance and other wheels from heat while drawing the temper from staff or pinion for the purpose of pivoting.

[Illustration: _Fig. 128._]

[Illustration: _Fig. 129._]

=305.= =Beat Block.= This simple device obviates the necessity of marking the balance to see that it is in beat. Before taking off the hair spring lay it on the block, shown in Fig. 129, turn the balance so the roller pin hits on the side the arrow points, then turn the table so that the line comes under the stud. In replacing the balance put the stud over the line and it will then beat the same as before. By using this tool you also avoid getting the balance out of true.

=306.= =Female Centers.= Centers are of two kinds,, male and female. The ordinary centers that accompany the lathe, which are male centers, are familiar to all watchmakers. Female centers, however, are not so well known among watchmakers, and they can be used to great advantage in many operations where other and less simple attachments and means are usually resorted to. You should have at least six pairs of female centers, the largest being one-fourth of an inch in diameter, which will accommodate as large a piece as you will wish to handle on your watch lathe, viz: winding arbors for clocks. These female centers are made from steel tapers, the same as male centers are made, but instead of turning the end to a sharp point they are countersunk, Fig. 130. First place the taper in a chuck and turn off the outside and end true; drill a small hole in the center of the taper, while the lathe is running, and deep enough so the countersink will not reach the bottom of the hole, or one-eighth of an inch deeper than the countersink. Harden the end only, and after tempering polish off the bluing. After you have made all the sizes you require, test all of them in your lathe to make sure they did not get out of true in tempering.

[Illustration: _Fig. 130._]

These female centers are very useful for holding or suspending any article in the lathe that is too large to be held in the split chucks. Pivots of clocks can be turned and polished very quickly and accurately in these centers.

Almost any kind of large work can be done on a medium sized watchmaker’s lathe by fitting to it a face plate one and three-fourths inches in diameter, with four slots, and fitted to a chuck with a standard taper hole to receive both male and female centers interchangeably. With two styles of dogs, almost any kind of large clock work can be readily handled.

These centers prove very useful for many odd jobs. As an example: It is a very common occurrence to hear an American clock beat irregularly, caused by the escape wheel being out of round. Select a pair of female centers that will admit the ends of the pivots of the escape wheel snugly; place one center in the taper chuck and the other in the tail stock spindle, and suspend the escape pinion in these centers; fasten on a dog, run the lathe at a high speed and hold a fine sharp file so it will touch the teeth of the ’scape wheel slightly, and in a moment the wheel will be perfectly round, after which sharpen up the teeth that are too thick.

[Illustration: _Fig. 131._]

=307.= =Drill Rest.= In using the lathe for drilling, a great saving in both time and drills can be effected by using a drill rest similar to that shown in Fig. 131. It is well to have a half dozen different sizes, starting at ¼ inch and increasing by ■ inch, for various classes of work. These rests are not kept by material dealers, but can be made by the watchmaker. Saw from a piece of rolled sheet brass, say 1-16 inch thick, the circles required, leaving metal enough to finish nicely. Place a steel taper plug in the taper chuck of your

lathe and turn down a recess, leaving a shoulder on the taper. Drill a hole through the brass plate to fit the steel taper tightly. Place the end of the taper on a lead block and proceed to rivet the brass plate, on the taper, making sure that it is true replace the taper in the lathe chuck and proceed to turn the face and edge of the brass plate perfectly true and to the proper size. Those who have tried to drill a straight hole through an object by holding it in the fingers know just how difficult it is to do, but by placing one of these drill rests in the spindle of the tail stock, placing the article to be drilled against it and bringing it up against the drill, you can drill the hole perfectly upright and avoid all danger of breaking the drill.

[Illustration: _Fig. 132._]

=308.= =Filing Fixture or Rest.= These rests will be found very convenient in squaring winding arbors, center squares, etc. There are several makes of these tools, but they are all built upon the same principle, that of two hardened steel rollers on which the file rests, and Fig. 132 is a fair example. One pattern is made to fit in the hand rest after the =T= is removed, while the other is attached to the bed of the lathe in the same manner as the slide rest. The piece to be squared is held in the split or spring chuck in the lathe, and the index on the pulley is used to divide the square correctly. Any article can be filed to a perfect square, hexagon or octagon as may be desired. The arm carrying the rollers can be raised or lowered as required for adjustment to work of various sizes.

=309.= =Filing Block.= A contrivance made to take the place of the filing rest, which was made of box wood or bone. Ide's filing fixture, shown in Fig. 133, consists of a cylinder of hardened steel, riveted upon a staff which in turn enters a split socket. The surface of the steel cylinder is grooved with various sizes of grooves for the different sizes of wire, or to suit any work.

[Illustration: _Fig. 133._]

[Illustration: _Fig. 134._]

Fig. 134 illustrates Melotte's revolving bench block, which combines both anvil and filing block. No. 1 is a steel anvil which may be instantly revolved and stopped on quarters. No. 2 is a rubber block, held by friction on its arm, and can readily be turned to any position. This rubber, being slightly elastic, makes a very suitable filing bed for small articles of any material and may be used without risk of scratching or defacing polished surfaces. No. 3 is a wooden block, held on to its arm by a spring friction device, which also allows it to be turned around to any desired position. The three-armed hub is revolved by pulling out slightly and is automatically held perfectly firm and solid in any of the three positions.

[Illustration: _Fig. 135._]

=310.= =Micrometer Caliper.= Fig. 135 is a full size cut of the Brown & Sharp Mfg. Co.'s micrometer caliper. It measures from one-thousandth of an inch to one-half inch. It is graduated to read to thousandths of an inch, but one-half and one-quarter thousandths are readily estimated. This instrument is also graduated to the hundredths of a millimeter, but when so graduated the table of decimal equivalents is omitted. They are also made to read to ten thousandths of an inch. The edges of the measuring surfaces are not beveled, but are left square, as it is more convenient for measuring certain classes of work. It will gauge under a shoulder or measure a small projection on a plain surface. Watchmakers will especially appreciate micrometers of this form. This tool will be found very useful for gauging mainsprings, pinions, etc. In the caliper, shown by cut, the gauge or measuring screw is cut on the concealed part of the spindle C, and moves in the thread tapped in the hub A; the hollow sleeve, or thimble D is attached to the spindle C and covers and protects the gauge screw. By turning the thimble, the screw is drawn back and the caliper opened.

The pitch of the screw is 40 to the inch. The graduation of the hub A, in a line parallel to the axis of the screw, is 40 to the inch, and is figured 0, 1, 2, etc., every fourth division. As the graduation conforms to the pitch of the screw, each division equals the longitudinal distance traversed by the screw in one complete rotation, and shows that the caliper has been opened 1-40th or .025 of an inch. The beveled edge of the thimble D is graduated into 25 equal parts, and figured every fifth division 0, 5, 10, 15, 20. Each division when passing the line of graduation on hub A, indicates that the screw has made 1-25th of a turn, and the opening of the caliper increased 1-25th of 1-40th, or a thousandth of an inch.

Hence, to read the caliper, multiply the number of divisions visible on the scale of the hub by 25, and add the number of divisions on the scale of the thimble, from zero to the line coincident with the line of graduation on hub. For example: As the caliper is set in the cut, there are three whole divisions visible on the hub. Multiply this number by 25, and add the number of divisions registered on the scale of the thimble, which is 0 in this case, the result is seventy-five thousandths of an inch. (3 × 25 = 75 0 = 75). These calculations are readily made mentally.

[Illustration: _Fig. 136._]

=311.= =Registering Gauge.= The registering gauges shown in the illustrations are two of the best examples of this class of tools. They are manufactured by A. J. Logan, Waltham, Mass., and are very accurate and nicely finished. Fig. 136 is an upright and jaw gauge, and Fig. 137 is designed as a jaw and depth gauge. They are both made to gauge one-thousandth of a centimeter or one-thousandth of an inch. Fig. 137 shows the piece of work marked A being gauged, while B represents a sliding spindle to get the depth of a hole or recess, or the thickness of any piece of work, which will be indicated on the dial.

[Illustration: _Fig. 137._]

[Illustration: _Fig. 138._]

[Illustration: _Fig. 139._]

Another form of registering gauge is shown in Fig. 138. It is an English gauge and but little used in this country. The principle of its construction, however, is good, and any ingenious watchmaker can make it. The back of the dial is recessed and arranged as in Fig. 139. One limb is fixed; the other is pivoted, and has a few rack teeth meshing into a center pinion. The pinion carries the hand, which should make a revolution in closing the calipers. The spiral spring attached to the pinion is to keep it and the hand banked in one direction for shake. The spring _s_ is to keep the jaws open. The milled headed screw and the clamp _c_ are to fix the jaws in case it is required to do so. A cover is snapped into the recess, and takes the back pivot of the pinion.

[Illustration: _Fig. 140._]

=312.= =Staff Gauge.= The tool shown in Fig. 140 is designed for measuring the height of the balance staff from the balance seat to the end of the top pivot. The illustration is enlarged to give more distinctness. _E E′_ is a piece of curved steel about ½■■ of an inch thick, and ½■■ of an inch wide. On the lower side from _E′_ to the end, the arm is filed down in width and thickness to correspond to an ordinary balance arm; _C_ is a slot in the upper arm _E_, which allows _A_, _B_, _D_, _A′_ to be moved backward and forward. _D D′_ is a round brass post drilled and tapped. The part _D′_ has a thread cut on it, and the part shown in the slot _C_ fits with easy friction. _B_ is a lock-nut, drilled and tapped to fit the thread on _D′_. It is for the purpose of clamping _D D′_ against the arm _E_. _A A′_ is a small steel screw with milled head, and is made to fit the tapped hole in _D D′_.

Mr. Beeton describes his method of using this tool as follows: Take your measurement of the distance _the balance seat is to be from the end of the top pivot_, as follows: remove the end-stone in balance-cock, and screw the cock on the top of the top plate (18-size full plate movement); then taking the plate in your left-hand, and tool (shown in Fig. 139) in your right, place _H_ in position, so that the end of the screw _A′_ rests on the jewel in the balance cock, and notice the position of the arm _E′_ which corresponds to the balance arm, between the top plate and under side of the balance-cock. If the distance between the arm _E′_ and end of screw _A′_ is too great, the arm _E′_ will be too low and touch the plate; if not enough, it will be too high and touch the regulator pins. Therefore, all that is necessary to do is to move the screw _A A′_ up or down as the case may be, sufficiently to ensure that the arm _E′_ will assume the position the _arm of the balance_ is to have. Take an 18-size balance with oversprung hairspring, the arm is at the bottom of the rim; in that case, when measuring, the screw _A′_ is adjusted so as to bring the arm _E′_ close to the plate, when _A′_ is resting on the balance jewel; if the balance is old style with undersprung hairspring, the balance arm is at top of rim, in which case _A′_ is adjusted so that the arm _E′_ is close to the balance cock; if the balance arm is in the center of the rim, as in some English and Swiss balances, the screw _A′_ is adjusted so that the arm _E′_ is midway between the plate and cock.

The reason the part _A_, _B_, _D_, _A′_ are arranged to move laterally in slot _C_ is, because all balance shoulders are not the same distance from the center, and where, in some cases, the screw _A′_ would be in a line with the center of the staff when the arm _E′_ was resting on the balance seat, in other cases it would reach past the center, of course, short of it; and, therefore, it is made adjustable to suit all cases.

[Illustration: _Fig. 141._]

=313.= =Staff or Cylinder Height Gauge.= The obvious advantage of this tool, which is shown at Fig. 141, is the automatic transfer of the measurement so that it may be readily applied to the work in hand. The tool, as the illustration shows, consists of a brass tube terminating in a cone-shaped piece. To the bottom of this cone is attached a disc through which a needle plays. Around the upper end of the tube is a collar upon which is fixed a curved steel index finger. A similar jaw, which is free to move, works in a slot in the tube. The movable jaw is tapped and is propelled by a screw that terminates in the needle point. This tool is very useful in making the necessary measurements required in putting in a staff. To use it in this work, set the pivots of the gauge through the foot hole, and upon the end-stone project the needle such a distance as you wish the shoulder to be formed above the point of the pivot. Next set the gauge in the foot hole as before, and elevate the disc to a height that shall be right for the roller, which is done by having the lever in place, the little disc showing exactly where the roller should come. Finish the staff up to that point; then take the next measurement from the end-stone to where the shoulder should be, for the balance to rest upon. This point being marked, the staff can be reversed and measurements commenced from the upper end-stone, by which to finish the upper end of the staff. Distances between the shoulders for pinions and arbors can be obtained with the same facility, a little practice being the only requisite.

=314.= =Vernier Caliper.= Fig. 142 is an illustration of the Vernier Caliper, a light, convenient and valuable instrument for obtaining correct measurements. The side represented in the illustration is graduated upon the bar to inches and fiftieths of an inch, and by the aid of a Vernier is read to the thousandths of an inch (see description below). The opposite side is graduated to inches and sixty-fourths of an inch. The outside of the jaws are of suitable form for taking inside measurements, and when the jaws are closed, measure two hundred and fifty thousandths of an inch in diameter.

[Illustration: _Fig. 142._]

These instruments can be furnished with millimeters (in the place of sixty-fourths of an inch), and provided with a Vernier to read to one-fiftieth of a millimeter.

On the bar of the instrument is a line of inches numbered 1, 2, 3, each inch being divided into tenths, and each tenth into five parts, making fifty divisions to one inch. Upon the sliding jaw is a line of divisions (called a Vernier, from the inventor's name), of twenty parts, figured 0, 5, 10, 15, 20. These twenty divisions on the Vernier correspond to extreme length with nineteen parts, or nineteen-fiftieths on the bar, consequently each division on the Vernier is smaller than each division on the bar by one-thousandth of an inch. If the sliding jaw of the caliper is pushed up to the other, so that the line 0 on the Vernier corresponds with 0 on the bar, then the next two lines on the left will differ from each other one-thousandth of an inch, and so the difference will continue to increase one-thousandth of an inch for each division till they again correspond on the twentieth line on the Vernier. To read the distance the caliper may be open, commence by noticing how many inches, tenths and parts of tenths the zero point on the Vernier

has been moved from the zero point on the bar. Then count upon the Vernier the number of divisions until one is found which coincides with one on the bar, which will be the number of thousandths to be added to the distance read off on the bar. The best way of expressing the value of the divisions on the bar is to call the tenths one hundred thousandths (.100) and the fifths of tenths, or fiftieths, twenty thousands (.020). Referring to the accompanying cut, it will be seen that the jaws are open one-tenth of an inch, which is equal to one hundred thousandths (.100). Suppose now, the sliding jaw was moved to the left, so that the first line on the Vernier would coincide with the next line on the bar, this would then make twenty thousandths (.020) more to be added to one hundred thousandths (.100), making the jaws then open one hundred and twenty thousandths (.120) of an inch. If but half the last described movement was made, the _tenth line on the Vernier_ would coincide with a line on the bar, and would then read, one hundred and ten thousandths (.110) of an inch.

[Illustration: _Fig. 143._]

=315.= =Hair Spring Stud Index.= Fig. 143 illustrates Johanson's hair spring stud index. The engraving shows the full size of the tool, which consists of a steel plate mounted on feet, and pierced with a number of holes for the reception of screws, when taking down a watch. In the center of the index is a hole for the staff, and an oblong slot for the reception of the roller jewel. To get any American movement in beat, proceed as follows: In front of No. 100 is a small spring; push same towards No. 10; then place the balance on top of the stand, with staff in center and roller jewel in the oblong hole; let the spring back gently; the balance will then take its own position. Set degree hand in front of the desired degree, as per direction on index table; place hair spring stud in front of degree hand, and push on the collet.

=316.= =Oil-cup Drills or Chamfering Tools.= The reservoirs that contain a supply of oil at the ends of pivot holes are made in the lathe with a semi-cylindrical drill, or by hand with a chamfering tool of the form shown at B or C, Fig. 144. A drill gives a clean cut, but necessitates a subsequent polishing of the hole; as to the chamfering tool here referred to, some inconvenience will be experienced in its use, owing to the point being apt to jump out of the hole and make irregular scratches on the brass, which are difficult to remove.

[Illustration: _Fig. 144._]

[Illustration: _Fig. 145._]

The best shapes of drills for making, or at any rate for re-forming or finishing oil-cups, are shown at D and F, Fig. 144, and in Fig. 145.

D and F are two drill-blades that terminate in non-cutting circular arcs. The flat curved end is more and more inclined from the top towards the corner, from _i_ towards the side _e_; the angle at _i_ becoming more acute, and at _e_ more obtuse towards the corners. The drill will, of course, only cut when rotating in one direction; in the other direction the obtuse angles and the reverse sides of the cutting angles will act as burnishers. Thus if the angles on either side are well formed and the blade has been polished, the surface of the oil-cup will be clean cut and polished. F is similar to D, but made from a steel rod.

=317.= _Observations on making the oil-cups._ Reservoirs that are made with a drill, or with a chamfering tool by hand, will often be found to be eccentric, and, when a pivot-hole is bushed and re-drilled, it proves to be struck from a different center from the oil-cup. In such cases watchmakers often give themselves endless trouble without securing a cup of good form and well centered. This difficulty can be avoided by using the tool in a lathe driven by a wheel; then, holding the plate in one hand square against a drill rest in tail stock, advance the tail stock with the other hand so as to bring the plate in contact with the drill.

When it is only required to correct the form of an oil-cup, the drill may be replaced by a rod with file cuts on its rounded extremity (H, Fig. 144). The reader will find no difficulty in making such a cutter for himself, drawing a file with both hands over the rounded end, but always in the direction of the file-cuts. After covering the surface with lines in this manner, rotate the cutter through a right angle and form a number of cross cuts. Or roughen the surface with a chisel of the form shown at H; after making a few cuts parallel to each other, turn the chisel through an angle and repeat the operation.

=318.= =Chamfering Tool.= As is well known, this is used for removing the roughness that a drill leaves at the edge of a hole, or to take off the cutting edge around a screw head sink, etc., thus forming a bevel edge. The tool commonly has a flat semicircular blade, the diameter of which depends on size of hole to be made; this semicircle is ground to a cutting edge like a drill, as shown at A, Fig. 144. Chamfering tools are also made pyramidal, with flat faces, as at B and C; the angle at the apex is more or less acute, according to the depth of chamfer required.

The oil-cup drills D and F are also used for chamfering the edge of a hole.

A cone formed at the extremity of a piece of pinion wire with a cutting edge on each leaf and hardened will be found very useful for this purpose.

=319.= The two forms of chamfering tool first described leave a series of undulations on the bevel edge, so that, instead of being conical, it presents a number of small facets. This inconvenience can be avoided by using the tool shown at Z, Fig. 145.

A small disc of hardened steel is pivoted within a recess formed at the end of a rod, the pin on which it rotates being at right angles to the direction of the rod. As is seen in the figure to right of Z, the section of this roller is a rectangle, and the surface is carefully polished, the edges being left sharp.

Clockmakers make use of a tool for forming oil-cups that only differs from the one above described in two particulars: (1) The disc is fixed on its axis; and (2) the edge, instead of being square to the two faces, is inclined as shown at _j_ and at the same time is slightly rounded crosswise.

A few trials will be found necessary before the most convenient thickness and inclination of edge are arrived at.

=320.= =Hollow Chamfering Tools.= These, as is well known, are used for removing the angles at the ends of cylindrical rods, of steady-pins, etc., or for rounding them off. Three forms are shown at O, Q, N, Fig. 146.

[Illustration: _Fig. 146._]

O is a round rod, the flat end of which has been filed across with the corner of a triangular file. Four cutting edges are thus produced which will act on the end of any object that rotates within them, or _vice versa_. If it be required to form a very acute angle, two slits must be cut with a screw-head file and the sides afterwards inclined to the required extent with a flat file. This tool will serve a double purpose: (1) to chamfer off the edge of a rod; and, (2) by prolonging this operation to form a point at the end.

As a rule, when it is desired to round off, say, a pillar of a clock after reducing its length or from any other cause, a hollow chamfering tool of very open angle is used, a rocking motion being imparted to it round the axis of the spindle; it is better to use a tool of the shape shown at N or Q. The latter, Q, is easily formed by strokes of a rat-tail file at right angles across its end; the other, N, is cut internally with a shaped chisel or with a small rotating cutter to which different inclinations are given during the cutting, as is also done when using the chisel.

=321.= The tool shown at O, Fig. 146, has been modified as follows by M. Roze. The two notches at right angles are replaced by three equidistant notches of equal depth. To make these in a piece of round steel it should be divided on the circumference into six equal parts; then cut the three notches as follows: Calling the points marked on the circumference 1, 2, 3, 4, 5, 6, one notch will lie parallel to the line joining 1, 3, and equidistant between this line and the point 5; a second will be parallel to 3, 5, and midway between that line and point 1, and the third will be parallel to 5, 1, and midway between this and the point 3.

In a hollow chamfering tool thus constructed it will be found that only the three long sides 1, 3, 5, actually cut, and at 2, 4 and 6 are short sides that are set back. But when a file is laid on the face joining two of the former sides, say 1, 3, the short faces 4, 6, will protect the cutting edge 5 from contact with the file.

=322.= =Tool for Centering Rods.= These appliances are well known to watchmakers, who often employ them for marking the position of the hole in the brass wire when making bushings. It is advisable to have such a tool somewhat large, about a third as large again as that shown at _s r_, Fig. 147.

[Illustration: _Fig. 147._]

The head of the centering punch or drill is filed flat on either side, and this flattened portion passes into a notch in the spring _r_, which maintains it in position and prevents rotation when the triangular-pointed blade is pressed against the end of this rod, this rod being caused to rotate in the hollow cone of _s_. Instead of a spring such as _r_, a helical spring is often used; but it then becomes necessary to fix a pin in the drill that slides in a groove in _s_, so as to prevent the drill from rotating.

=323.= =Centering with a Set-Square.= The set square may be used for centering round rods, and the following is a very simple mode of applying it:

[Illustration: _Fig. 148._]

On one arm of the square R, Fig. 148, a triangular plate _c d_ is screwed or riveted so that its edge _c d_ exactly bisects the right angle, that is, divides it into two equal angles. The flat end of a round rod is held within the angle and against the plate, a line being traced on it along _c d_; it is then turned through about a right angle and a second line traced. The intersection of these two lines gives the axis of the rod.

=324.= =Tool for Roughing Out Points.= This is merely the inverted chamfering tool of which two forms are described in paragraphs =320-21=, one of them being also shown at O, Fig. 146. It will be evident that when the end of a rod is caused to rotate in this hollow cone it will take its form.

In some cases it may be found convenient to place such a tool in the tail stock of the lathe.

If the bottom of the cone at the end of O were prolonged by continuing the cuts farther down with a thin flat file, the point of the rod might be formed like a conical-headed screw before it is tapped.

=325.= =Balance-spring Collet Tool.= This convenient little tool for rotating the balance-spring collet is commended almost as much by its simplicity and facility of construction as by its usefulness.

[Illustration: _Fig. 149._]

A steel rod _n_, Fig. 149, is fixed in a handle T; it terminates in a cone _a_ and is drilled with a fine hole as indicated by the dotted lines. A thin wing _b_, pointed at its extremity, is also attached to the handle.

Holding the balance between the fingers of the left hand and the tool in the right, the blade _b_ is introduced into the slit in the collet while _a_ rests on the balance staff shoulder, the pivot being within the hole _n_. Now rotate to the right or left until the stud is opposite to the mark on the balance rim, and this may be done without danger, providing the tool is held firmly and vertical.

[Illustration: _Fig. 150._]

=326.= =Watch-hand Holder.= A very convenient form of tool, in which to clamp a hand while enlarging the center hole is represented in Fig. 150. Two brass plates, _f_ and _g_, are hinged at _m_ like a sector. A collar, _a b_, surrounding the two is pivoted at _a_ and has a clamping-screw _b_ by which the two plates can be forced together. Several circular sinks of different sizes and equally divided between the two plates, are cut of a depth varying from one-half to two-thirds that of the plates, and they must be made to increase in diameter as they get deeper, thus resembling the internal groove that receives a barrel cover. The plate _a_ is cut away along the portion _c d_ and grooves are formed to leave passages open between this surface and the bottom of the sinks in _g_ and _f_.

When it is required to enlarge the hole of a watch-hand, place it, inverted, in the hole of suitable size, as shown at _c_ of the figure, and tighten the screw _b_. Held round the whole or greater part of its circumference, the hand is thus firm and its center hole can be enlarged without risk, either with a drill or broach; the hand will not show marks due to the pressure with which it has been held.

=327.= =Common Hand fitting Pliers.= The sliding tongs with large flat head, perforated with a number of holes in which the head of a hand is clamped when the opening requires to be enlarged, are often useful, but we feel them to be less so than the holder just described. It is desirable that the inner faces of their jaws, which are usually left rough, be at least smoothed.

[Illustration: _Fig. 151._]

=328.= =Another form of Watch-hand Holder.= M. Fiquemont has devised the simple little tool shown in Fig. 151. It consists of a short brass rod R, perforated lengthwise and having a thread cut externally on the surface _a b_. It should be reduced in thickness below this tapped portion. The rod, shown also in longitudinal section at P, is cut into four quarters by two slits from _a_ to _b_, which are at right angles and leave the points as indicated apart at _d_. The elasticity of these four quarters should make them take the form of a reversed cone when holding a hand, so that the ascent of the screw _c_ shall tighten them.

Within the head _a_ of the tool is formed a circular recess, so that, if the reversed head of a watch-hand be placed within it and the screw made to ascend, it will be held very firmly by the circumference, as seen in the figure. The hand will thus be perfectly free to adjust in any way that is needed for fitting it while held at the end of the tool, and without being removed before the work is complete. Three or four sizes will suffice for all ordinary watch-hands.

A tool may be made in a similar manner, except that the screw is not divided by the longitudinal slits, and the hand is held against the point by a lantern (similar to those of a screw-point tool), which must be cut away in the manner indicated in Fig. 150, explained above (=326=). An assortment of three or four lanterns will render the tool serviceable for all sizes of hands.

[Illustration: _Fig. 152._]

=329.= =Clip for Holding Escapewheels while Cleaning.= A mere inspection of M, Fig. 152, will make the arrangement of this little tool evident. The fork is made of a piece of brass rod and its two arms are elastic, a handle being screwed into the lower extremity.

Two small steel jaws are fixed to the upper ends inclined towards each other, and, in using the tool, it is only necessary to press with two fingers on the heads of the screws, when the jaws will open. Having placed the escape wheel pinion between them, the wheel will be firmly held so that its teeth can be easily cleaned, etc.

[Illustration: _Fig. 153._]

=330.= The appliance shown in Fig. 153 can be used for a similar purpose, and is further especially serviceable for holding an escape-wheel that is not riveted to its pinion. It consists of two parts, a handle T, shown separate at _t_, which is drilled throughout its length and tapped externally at the portion _t_, and a collar or nut D, the end of which is traversed by two cuts at right angles that resemble the letter =T= in section. If the tool is intended for holding escape-wheels that have three instead of four arms, this cross must be replaced by three radiating grooves of similar section. The position occupied by the wheel is indicated by the dotted lines _r r_, and it will be evident that, when the flat end of T is screwed up against this wheel, after dropping it into the cross and slightly turning round the axis as in a bayonet joint, it may be firmly held. The safest mode of introducing the wheel is by holding it on a broach, which is subsequently removed.

[Illustration: _Fig. 154._]

=331.= =Tool for Testing the Truth of a Cylinder Escapewheel.= The small tool shown at D, Fig. 154, can be advantageously used in place of the plain arbor commonly employed for testing the equality of the spaces in such a wheel. The plate D, which may be mounted on three feet, is traversed at its center by the smooth conical portion _f_ of the screw _f v_, tapped somewhat tightly into a cock fixed to the other side of the plate. There is a radial slot, _a c_, cut in the plate large enough to allow an escape-wheel pinion to move freely. An inspection of the figure will make evident the manner in which the tool is to be used: a wheel being placed as shown, or with reverse side upwards, is made to slide towards the center, gradually raising the screw until the largest space is found to admit _f_ with contact at both sides. All the smaller spaces are then carefully opened until they admit the cone in the same manner as the largest.

=332.= _Novel tool for the same purpose._ When the spaces are adjusted in the manner explained above, or if the length of the teeth is measured in a narrow gauge plate, there will nearly always remain a certain degree of irregularity in the teeth. A more efficient means would be for the gauge to embrace both a tooth and space, and this condition is satisfied by the following appliance.

[Illustration: _Fig. 155._]

The slide _k k_, Fig. 155, is dovetailed into a plate, level with its surface, so that _k k_ can be moved in a vertical direction by a screw; it is perforated with a series of holes of gradually decreasing diameter. To the same plate are also fixed: (1) a smooth tongue, _b_, with a foot and screw; and (2) a second tongue, _j_, terminating in an index _x n_, which is movable about a pivot, _x_, and held against a pin in the plate by a light straight or spiral spring. The extremity, _n_, traverses a graduated arc.

Having introduced the pinion of the wheel, or the arbor on which it is held, into a hole of the slide that it fits without shake, and brought this hole to the position indicated in the figure, apply a slight pressure to the wheel in the direction of its rotation. With one tooth resting against _b_ the tongue _j_ will be held by the spring against the next and the reading of the index is to be noted accurately. Withdraw the wheel slightly, and, placing the succeeding tooth against _b_, take a second reading, and so on around the entire circumference.

Of course, the delicacy of the instrument will be increased by lengthening _x n_ in comparison with _x j_.

[Illustration: _Fig. 156._]

=333.= =Tool for Removing Studs.= Fig. 156 represents a small tool which may be employed for this purpose. It consists of a thick strip of metal, C, spreading out like the letter T at the end which is not shown, so as to form two feet, the screw, _j_, being a third, so arranged that the T rests horizontally. The disc, _d_ (shown also in plan), rotates on the screw, _j_, and is partially enclosed in a horizontal slot. Around the circumference of _d_ are four rectangular notches of different sizes. The holes indicated by black dots on the plan receive the point of the screw, _v_, which clamps the disc when the notch corresponding in size with the stud to be removed has been brought under the small cone projecting from the spring, _b_; the other end of _b_ is fixed to the T-shaped piece, C. The mode of using this little instrument will at once be evident. Resting the right arm on the bench, and, with the left-hand, bringing the wing of the cock above the notch in _d_, the other hand presses upon the milled button of _b_, forcing the conical pin against the stud and thus removing it from the cock. The screw, _a_, can be adjusted so as to prevent too great force being applied.

[Illustration: _Fig. 157._]

=334.= =Tweezers for Removing Studs.= One form is shown in Fig. 157. The upper arm, H, is bent downwards as indicated at _g_. The lower arm is shorter and carries a separate piece, _n m_, which slides under two screws, _s_, and is pressed forward by a spring, _r_. The action will be easily understood; the extremity, _m_, rests against the stud, and _m n_ is forced backwards until the point, _g_, is exactly over the stud pin. A simple pressure of the finger will then suffice to remove the stud.

A still more simple pair of tweezers for this purpose may be made by filling a square notch in the end of one prong of an ordinary pair with broad noses, and setting a pin opposite to its center in the end of the other prong.

=335.= =Staking Tool.= The modern staking tool will perform the same work as the last two tools described and many other operations. It consists of a shifting table, around which holes of various sizes are arranged in a circle, so that any desired hole may be brought under a suitable punch moving in a vertical holder. Usually twenty-four tempered steel punches and four stumps are provided, which will be found sufficient to cover all the operations in the ordinary run of watch repairs, and the ingenious workman can from time to time add to these by making punches in his spare moments, if he finds from experience that he is in need of punches of a different shape. Fig. 158 illustrates the Johanson combination staking tool, on the front end of which a hairspring stud indicator is arranged.

[Illustration: _Fig. 158._]

=336.= The staking tool can be used as a cannon pinion tightener by making a punch for it having a blunt chisel edge. When a cannon pinion is placed on a stump which is slightly dished in that portion of its face opposite to the punch, and the punch gently struck with a hammer, it will be sufficiently contracted to insure the requisite adherence to the set-hands arbor. If fears are entertained lest the pinion should be cracked with the blow, it may be placed loosely on an arbor and held in position.

=337.= It may also be used to advantage for tightening the set-hands arbor in the center or cannon pinion, but care must be exercised or the arbor may be bent so that the minute hand which it carries passes nearer the dial at one place than another.

An arbor that is too loose is introduced into a suitable stump and at the top and bottom of the slack portion two punch marks are made opposite one another. The punch having a conical or three-sided point, will occasion an expansion of the metal round each mark; if a smooth file be passed over the surface so as to remove the burr, which would not offer any permanent resistance, sufficient projecting metal will be left to secure a sound and lasting friction when a little oil is applied.

If the arbor is well supported immediately beneath the punch, it will not be distorted by any moderate impact. It is advisable before operating on the metal to ascertain its degree of hardness.

=338.= It may also be used as a pinion riveting tool. The pinion, with its wheel in position, is placed on the hardened steel stump, the end to be riveted being upwards. The riveting is then struck with the polished end of a hollow punch. If it be required to spread the riveting, a punch must first be used that is rounded from within outwards, to be followed with a perfectly flat punch. A little practice will at once enable a workman to select the best form of punch.

The stump should be very hard and polished, funnel-shaped downwards and carefully fitted to the bed, so as to be firm and central with the punch. If these precautions are not taken the pinion will spring and the riveting will be imperfect.

=339.= The staking tool may also be used for closing up barrel holes, screw-holes, etc. In repairing watches it is often found that the screws hold badly or not at all, and the holes at times cannot be satisfactorily bushed. In such cases it becomes necessary to close them, an operation which any intelligent workman can perform very well in the following manner: Make a stump rounded at the top and provided with a pump-center. This can be merely a pointed steel rod that passes through the stump from below with slight friction, and is forced upwards by a light spring fixed by a screw, so that, on undoing the screw, the rod can be removed. The one pump-center can be used for various stumps as the openings are funnel-shaped downwards. Center the hole to be closed by means of the pump-center, then bring down the hollow punch and strike it as in riveting a pinion. A small circular groove will be formed around the hole, which, if the punch is in good order, will be perfectly even. The form of the punch is very important; the watchmaker must decide for himself by trial as to the most convenient shape. The thickness of the ring of metal may be modified; it is rounded off in a semicircle by some, and curved inwards or outwards by others.

Instead of a pump-center below we have used punches that were themselves provided with a pump center and helical spring. Either form gives satisfactory results.

The holes of barrels can be closed with a punch that is only depressed at its center enough to avoid the point of the pump-center. When the face is more or less rounded the hole will be closed by forming a cup as with a chamfering tool. The tool may then be enlarged if requisite with a round broach or an arbor covered with white wax. It will thus be hardened, and the cup-shaped recess will serve to retain the oil, while the somewhat thinner hole will probably be in a condition to resist friction as long as formerly.

When the hole is of moderate thickness, and it does not require much reduction in diameter, this method will be found satisfactory; barrels that have been thus treated have been found to stand ten years without appreciable wear. When the metal is thicker, however, the spreading inwards is very slight, and there is some danger, in using a round broach to do it, of straining the metal or detaching the central ring of the barrel or its cover.

It should be observed that the methods explained above are absolutely useless for closing pivot-holes, and should only be resorted to for barrels, on an emergency.

=340.= =Drifting Tool.= This appliance, shown in Fig. 159, is very useful for making holes of round, oval or square, or, indeed, any required form. It takes the place of a punching machine for light work.

[Illustration: _Fig. 159._]

The punch, or “drift,” is screwed into the stock C C′. A pin, _p_, fixed in C C′ prevents its rotation while allowing an end motion along the slot _m_ _n_. The end C′ is hollowed out to receive the point of a screw, B, and a pin, shown near C′, is received in a groove turned in B, thus enabling it to draw the stock in the direction C C′. The part H is gripped in the jaws of a vise, and a strong handle, E, is used to advance the screw B B′. With a tool about three times the size of the figure there is no difficulty in punching the eyes of mainsprings, square holes in stop fingers, etc., and it can be made by an apprentice. Of course its strength depends on the pitch of the screw and the radius of the handle E.

=341.= For heavier work it will be necessary to resort to the punching machine. There are several constructions in use, but the most usual is essentially the same as that of the tool just described. The screw works vertically in a strong bridge that is fixed to the bed in which the counterpart of the punch is held. Great use is made of this machine in factories at the present day, almost every part of a watch being in the first instance roughly shaped by its means. Indeed, thin metal is often left as it comes from the punch, and very perfect crossings of wheels, etc., are thus produced.

Steel does not cut well in the press unless it is soft and homogeneous, and the final dimensions of the object can be more nearly approached according as these conditions are satisfied. Attempts have been made to cut levers, etc., of the exact dimensions required, but it is better to leave a slight excess of metal to be afterwards removed by a mill cutter or other means. The crossings of steel lever and cylinder escape-wheels are punched out, but the metal used is of special excellence. Before introducing a piece of steel into the press it is advisable to remove any scale, etc., by pickling, or with a file.

=342.= =Draw-Plate.= Every watchmaker should possess a plate for drawing round wire so as to be able to obtain it of any required diameter. They are to be had at all material houses. In bushing holes in a brass plate, it not unfrequently happens that the brass used for the bushing is not of the same color as the plate. To avoid such a difference cut off a piece from a plate of the same color and round it by hand, making one end to taper. Fixing the draw-plate in the vise, pass this end through one of its holes, and, gripping it in the hand-vise, pull the brass through the plate. Continue this operation through successive holes until the requisite thickness is attained.

No special precautions are necessary, further than keeping the holes well greased and annealing the brass from time to time so as to counteract the hardening caused by the operation.

Such a plate can also be used for steel wire, and plates with holes of special form, for example those for drawing click and pinion wire, are well known in the trade.

[Illustration: _Fig. 160._]

=343.= =The Grammaire, or Dividing Plate.= This tool is shown in Fig. 160. To mark out the crossings of a wheel, etc., fix it by the conical-headed screw _t_ to the middle of the plate, on which are traced a series of concentric circles (not shown) divided into 6, 8, 10 and 12 equal parts. By laying the little ruler _r_ _r_ over the wheel blank and using these division marks as a guide, 3, 4, 5 or 6 radii can be drawn to serve as guides for cutting out the arms.

If it is desired to indicate the width of the arms instead of a mere central line, a series of holes must be drilled at the division marks and screws with tapered points tapped into them from below. Resting the ruler against these cones, the arms can be drawn of any required width, according to the distance to which the screws project. No further explanation is necessary, for the figure shows: (1) a grammaire adapted to mark out a four-armed wheel, these arms being indicated by the dotted lines; and (2) the small ruler _r_ _r_ cut away at the middle so as to avoid coming into contact with the conical-headed screw.

[Illustration: _Fig. 161._]

=344.= =Jewel-resetting Tools.= Hopkins' patent jeweling and staking tool, shown in Fig. 161, is an ingenious device, and one that will be found very useful to the watch repairer. As the spindle, or handle, to which the cutters and burnishers P P P are attached, is sustained in upright position when in use, by the long bearings through which it passes in the upright F, independently of the lower center, the hole to be cut may be centered either from above or below as preferred; and the depth to which it is desired the cutter shall work is regulated by adjustment of the sliding collar E, and this being a correct uprighting, as well as jeweling tool, with it a pivot hole, or a jewel setting, the correct center (upright) of which has been lost, may readily be corrected, or its true center again found, and, what in some cases would be a very desirable consideration, by careful manipulation with the cutter, which is under perfect control of the operator, the position of jewel settings may be changed so as to alter the depth of locking of the wheels to any desired extent. To regulate the depth to which it is desired a cutter shall work below the surface of a plate, lower the spindle D until, when moved out sufficiently far, the end of the cutter will rest down on the top of the plate to be operated upon, and fasten it there by lightly tightening the screw K; this done adjust and fasten the collar E on the spindle D, to the same height above the top of the upright F as it is desired the cutter shall work below the surface of the plate on which it now rests. This, when the spindle D has been again set free by loosening the screw K, will of course allow the cutter to sink into the hole to be operated upon to the exact distance the collar E had been set above top of F. In adjusting the collar, E, the graduated wedge No. 4, or the jewel to be set, as preferred, may be used as a gauge. The burnishers, No. 9, are used both for opening and closing settings; the same burnisher,

having chosen one of proper size, is used for both purposes; the side being used for opening the setting, and the beveled and rounded end for burnishing it down again over the jewel. The pieces 13 and 14 are made to fit in the lower end of the spindle D (the cutter P having been removed), same as an ordinary drill-stock, and are used for burnishing the edges of a jewel setting down flat over the jewel, countersinking screw heads, giving end-shake to wheels, etc.; and being easily made, any one owning the tool can make these for himself, of forms and sizes to suit the particular work in hand. For uprighting purposes, withdraw the spindle D and substitute No. 5, the rings, No. 3, being intended for laying the work on, on the tool bed. For upright drilling through watch plates, mark the place to be drilled (prick punch it slightly) with the cone point of No. 5; which done turn the spindle No. 5 upside down and rest the upper end of the drill in the countersink in its end, the drill being operated with a fiddle bow acting on a collet placed on its shank for the purpose. For cutting off bushings level with a watch plate, either a cutter of the No. 13 or 14 class, or one of the P cutters can be used. For staking or riveting wheels upright on their pinions, lay the stake No. 7 level on the tool bed (the center M having been fastened down out of the way), and with No. 5 center accurately the hole to be used in the stake, and fasten it there by means of the clamps N; then remove the cone end of No. 5, and place a punch with a hole in its end of the required size, on the part _m_, and proceed as in an ordinary upright staking tool.

=345.= =Tool for Flat Polishing.= A thick brass plate is provided with three strong screws arranged in triangular form (G, Fig. 162), and far enough apart to ensure that, if the plate is reversed and rests on their heads, it will remain flat when moved by hand over a polishing surface.

[Illustration: _Fig. 162._]

The screws should fit tightly or be provided with lock-nuts.

We believe that every watchmaker must be acquainted with this little tool. The object to be smoothed or polished is fixed with shellac or sealing-wax to the middle of the triangle formed by the screws; the level is then adjusted so that, when resting on a flat surface, the object to be polished coincides exactly with it. The polisher (for example, a sheet of ground glass) is charged with oilstone dust or polishing rouge, and the object is passed over it until perfectly flat and smooth.

=346.= For smoothing, it is best to use a large sheet of iron or steel. For polishing, copper or bronze is preferred. Ground glass may be employed for both operations; it must be hard and perfectly flat.

A disc rotating in the lathe or mandril, etc., is often used.

The tool may be inverted and rest firmly on a cork, the polisher being then moved backwards and forwards by hand, and always in contact with the three screws.

It is best to use pith for cleaning the polished surface; in its absence use soap, then wash and dry with a soft linen rag. The object is detached by heating the tool, and is cleaned by boiling in alcohol; afterwards pass through pure alcohol at the ordinary temperature and dry.

=347.= This tool can be employed for polishing small surfaces, such as the end of a rod, of a barrel-arbor or a screw-head, as well as for those of greater extent. But it appears needless to enter into further detail.

Instead of three screws some workmen only use two, at some distance apart. The object to be polished, being placed at the third corner of the triangle, takes the place of the remaining screw.

Lastly, if a band be fitted to one side of the brass plate, as shown at _b_, Fig. 162, and held by two screws, it will often be of service as a clamp for fixing the object, as at _s_.

=348.= Flat pieces can be polished on a revolving lap worked by the foot, being simply held in the hand or in a piece of soft leather; but a certain amount of practice is needed in order to do this successfully.

ACCESSORIES

AND MISCELLANEOUS OPERATIONS TO BE PERFORMED IN THE UNIVERSAL HEAD.

=349.= With a view to simplify the work, we will here give, in a collected form, a number of operations that may be performed in the mandril, or universal head, among which the practical watchmaker will easily be able to distinguish those that can be done in the

ordinary lathe; we will also describe numerous accessories that the workman should make for himself, if he is desirous of making his mandril or universal head still more generally useful.

[Illustration: _Fig. 163._]

=350.= Prepare a number of chucks of the form shown in Fig. 163. Some of these carry a small bar with screws, by which an object may be clamped firmly to the chuck, an arrangement which is also shown at A, Fig. 163; others have a hole drilled through their axis; others again have a projecting arbor, etc. They may also be made with a flat face on which to cement objects in the ordinary manner.

[Illustration: _Fig. 164._]

As it is often necessary to have a considerable surface to cement, for example, a watch-plate, one or more may be made of the form shown at T, Fig. 164. The lower plate being clamped in the dogs, the disc _e_ will be free. If this disc be made of bronze or steel it may be used as a lap; if of brass, it may be turned true and used as a wax chuck, etc.

The chucks should, as far as possible, be well made, so that they can be truly centered by means of the pump-center.

TO CENTER AN OBJECT.

=351.= When there is a hole at the center on the side towards the face-plate, in the universal head, as is usually the case, it is only necessary to place this hole over the point of the pump, pressing it inwards, and then to clamp the object in the dogs; the pump is then drawn within the body of the arbor. Very often, however, there is no central hole, or there is only a mark on the face that is towards the cutter; in such a case it becomes necessary to center from the front or by the circumference.

=352.= =To Center from the Front.= If the object is held by wax on a plate, it may be centered as in the ordinary lathe while the plate is hot, by resting a piece of pegwood on the T-rest with a point placed in the central hole, and observing whether its free end remains stationary.

After the plate has cooled, the accuracy of the centering should be tested by means of a long piece of pegwood which rests on the T-rest brought close up to the object. The pegwood is held parallel to the lathe-bed, and, if the centering is satisfactory, its outer end will not move. The detection of any slight movement is greatly facilitated by placing some fixed object close to the free end of the pegwood. If a motion is still observed the centering is imperfect, and must be corrected in the manner explained below (=354=).

=353.= _Perrelet's method of Centering._ In principle, this is identical with the one just described; but the pegwood index is replaced by the small apparatus shown in Fig. 165.

[Illustration: _Fig. 165._]

A hollow cylinder, of which _a c c a′_ is a section, is firmly held by friction by its portion a _b b′ a′_ in the tailstock. In the front of this cylinder is fixed a steel ring that is thick at the circumference and tapers inward, so that the central hole has a cutting edge. The two black triangles represent a section of this ring. The rod _r_ _n_ passes without play through this hole, and carries a projecting ring at _s_ to determine the distance to which it enters the collar _c c_; there is also a small key that corresponds with a nick in _c c_, and thus prevents rotation.

An inspection of the figure will show that, when _s_ rests against _c c_, if the finger be placed on _r_ and communicate motion to it, the rod _n r_ will be able to oscillate in any direction, and to an extent limited by the diameter of the hole in the cylinder.

The error in the centering at _r_ will be multiplied at _n_ in the proportion of _n s_ to _s r_; thus if _n s_ is ten times _s r_, the motion at _n_ will be ten times as great as the actual error at _r_.

=354.= The instrument is used as follows: The object to be centered being placed between the jaws, having the centering spindle in position in tailstock. Slide tailstock towards the face-plate until the point _r_ of the rod enters the hole, or central mark of the object, and, setting the T-rest close to the point _n_, rotate the face-plate. If the centering is exact, the point _n_ will remain stationary. If _n_ moves to and fro, give a gentle blow against the edge of the object, which should not be held firmly in the dogs; the blow must be on the side opposite to that at which _n_ shows the greatest deviation from the point of reference. Repeat the process until the centering is perfect or sufficiently accurate; then clamp the dogs firmly, taking care not to disturb anything.

In centering from a jewel hole, an aluminium rod _n s_ may be employed on account of its lightness, and it may be terminated in an ivory cone at _r_.

=355.= There is one precaution to be observed, as it facilitates the use of this appliance; it is advisable that the portion _a b b′ a′_ of the cylinder be somewhat long and well made, in order that, while being in the first instance inserted in tailstock up to the shoulder, the cylinder may be partially withdrawn and still held firmly. The reason for this is as follows: When the tailstock is pushed along, a considerable amount of friction resists its motion, and, as the hand cannot always control this motion, it may happen that _r_ comes up against the object with some force. To avoid this, bring the point near the hole and then rotate the collar in the tailstock so as to gently withdraw it to the requisite amount. The cylinder may, if desired, be fixed by a small screw after the point _r_ has been set in position.

[Illustration: _Fig. 166._]

=356.= =Another Centering Device.= The centering indicator shown in Fig. 166 will also be found useful for testing for exact center. The body of the indicator is made of sheet brass, and should be about five inches long by two inches in width at the larger end. The shank _C_ is made to fit in rest holder, and is either riveted or soldered to the body; _R_ is steel or copper wire sharpened to a fine point, and balances on a pivot at 1; _B_ is a clock hand pivoted to the body at 1; 2 and 2 are pivot joints only, and do not go through the body; _C_ will perhaps give a better idea of the end _R_. To center with this tool, unscrew your rest and remove it, then place the shaft _C_ in rest holder and adjust it till the needle point _R_ touches the top of hole, as shown at _A_. The index hand will then note the variations as the head revolves. If too low, the hand will point above center, and if high, vice versa.

=357.= =To Center from the Circumference.= Two cases may occur: Either the entire rim of the object is exposed, as when the teeth are to be cut in a wheel blank; or the rim can only be used as a means of determining the center, as when a barrel has been bushed with an undrilled bushing.

=358.= The tool shown in Fig. 166 may also be used for the test if the short end of arm R rests against the under side of the object that it is desired to center.

=359.= When it is required to drill or merely to center the hole in a wheel, barrel, etc., that does not run true, clamp a piece of sheet brass in the dogs and turn out a sink that will exactly receive the wheel, etc., but allowing it to project slightly. Now unscrew one dog and advance it a little, so as to grip the edge of the object as well as the plate; move the other dogs inwards in succession, and it will only remain to drill or true the hole with a suitable drill.

UPRIGHTING AND DRILLING.

=360.= =When the Lathe is Provided with a Tailstock.= Let it be required to mark and drill a pivot-hole in the cock when the plate-hole is accurately centered by means of the pump-center. Place the tailstock in position on the lathe-bed, and mark the position of the hole with a center, as in an ordinary uprighting tool; then, if the hole is to be very fine, make it with an ordinary pivot-drill.

If the hole to be drilled is somewhat large, it may be drilled with the twist drill, the bed of the lathe being, as usual, horizontal.

=361.= =When the Lathe is not Provided with a Tailstock.= In such a case it is possible to upright and drill by using fine drills, and making points so formed as to take the place of the cutter. Or a stock may be made to receive drills, points, etc., and it may be well here to remark that stocks of the same form are convenient for receiving chamfering or sinking tools.

[Illustration: _Fig. 167._]

This stock is shown in Fig. 167. An inspection of E _c_ will suffice to show its form, and it may be used for holding either a drill or a marking point, or a small hollow center in which to support a pivot drill.

The following method should be adopted for securing accuracy in the adjustment of these stocks:

There must be no shake of the stock in the tool-holder; it is especially important to avoid any displacement during the act of clamping. If there is any reason for doubt on this point, drill a hole at the foot of the cutter in which an index, _y_, can be temporarily inserted; any displacement can be detected by its deviation from a fixed mark. As a rule, however, there will be no occasion for

doubt if the plate that is screwed down upon the stock is parallel to the bed of the tool-holder.

The cutter is then replaced by a stock of the form shown at E′, in which a hole has been previously drilled to receive the drill or other bit, but somewhat smaller than it is required finally to be. The pump-center must now be replaced by an accurately fitting piece B that terminates in a short semi-cylindrical drill.

It will be evident that if the mandrel be revolved, and, at the same time, the tool-holder advanced towards this drill, the hole in the stock E′ will be enlarged and smoothed, and its axis will accurately coincide with that of B. Any drill, chamfering tool, etc., that has been turned true, will, therefore, on being inserted in the stock, prove to be strictly in the axis of the lathe.

[Illustration: _Fig. 168._]

=362.= =To Drill a Series of Holes.= Mount on a stock similar to that just described, a small frame carrying a drill-stock, as shown in Fig. 168. If this be fixed in the slide-rest in place of the cutter, it can be used for drilling a hole or a series of holes previously marked out, or, if the pitch of the transverse screw of the slide-rest is known, for a series of equidistant holes in a horizontal line. When it is required to drill a series of holes in a circle, as, for example, in the escape-wheel of the pin-escapement, bring the point of the drill onto the circumference and then proceed as when using the ordinary wheel-cutting engine provided with a vertical drill-holder, taking care to fix the face-plate by means of an index.

This index should have a means of slightly modifying its length, so that the point of the drill may always be brought into exact coincidence with the points that have been previously marked on the object.

It will be observed that, if the drill were replaced by a round milling tool, the U's of a cylinder escape-wheel might be polished, or, indeed, cut, the concave ends of the teeth of the star-wheel in a Geneva stopwork could be corrected, etc. But it is unnecessary further to insist upon the many uses to which this form of tool can be applied.

=363.= =To Cut the Teeth of a Ratchet, Minute-Wheel, Etc.= When the face-plate is divided on the circumference, it is easy to cut the teeth of an ordinary wheel of a timepiece, escape-wheel, barrel ratchet, to cut or true a star-wheel for the stopwork, etc. After mounting the wheel on a chuck and carefully centering it, replace the cutter by a small revolving cutter-frame after the model of that shown in Fig. 168.

The stock _d_, shown in both plan and elevation, carries a piece _c_ at right angles, which has a slot cut throughout its length. In this slot a U-shaped support can be clamped by a nut in any position. The U portion forms a bearing for a cutter, such as is shown at _f_ in the figure, and the axis projects so as to receive a ferrule for rotating the cutter.

It will be evident that, with such an arrangement, the height of the cutter can be adjusted in accordance with the teeth to be cut.

=364.= =To Cut a Circular or Elliptic Groove.= For this purpose no special accessory is needed; an ordinary cutter will suffice.

[Illustration: _Fig. 169._]

Let _a b c d_, Fig. 169, be the form of the required groove. Mark a series of centers so that circles struck from them will just overlap one another, and at the same time nearly reach the edge of the groove. Then turn out all the circular sinks, indicated by shaded lines, to the required depth.

Center the plate by the point _o_ from which the arc _a b_ is struck; now bring the cutter to such a position that its outer cutting edge coincides with the arc _a b_, and bring it against the plate; set the face-plate in motion, not, however, by using the treadle, but by the hand at its circumference, and traverse the arc from _b_ to _a_; then withdraw the cutter. By this means the projecting angles, left white in the figure, will be removed, and a clean edge will be left to the groove.

As an operation of this description will not present any difficulty, further explanation appears unnecessary; for the information above given will enable any watchmaker to make curved grooves of the kind indicated.

If it is required to smooth the surface of the groove, replace the cutter by a pegwood stick that can be rotated with friction, and the end of which just fits into the groove, charging it with pumice or other stone and oil. One hand moves the face-plate backwards and forwards, while the other rotates the stick.

[Illustration: _Fig. 170._]

=365.= _To Cut the Cylinder Escape-Wheel Cock Passage._ As a rule the cock is cemented, inverted, to a wax chuck, and the passage cut or enlarged on the lathe. It is more expeditious to use a plate provided with a clamping bridge, as shown at Fig. 170. The face-plate should be made to oscillate backwards and forwards by hand, and not rotated by the wheel.

=366.= =To Make a Straight Groove.= _First method._ The tool devised by M. Chopard, director of the school of horology at Besançon, and shown in Fig. 171, is used for this purpose. As will be seen, it consists of a small lathe which is adapted to the slide-rest as follows:

[Illustration: _Fig. 171._]

Two pins, _a a′_, are planted in the top of the tool-holder, the cutter together with the plate by which it is clamped having been first removed. Holes drilled in the frame _f f_ fit accurately onto these pins, while a screw, _h_, passing through an intermediate hole, affords a means of firmly fixing the apparatus to the tool-holder M.

This tool should satisfy the following conditions: The arbor C should fit into a recess that receives a cutter, but without coming into contact with it; this arbor should be parallel to the bed of the lathe; and, lastly, the axis of C should be on a line with the lathe center.

=367.= Having set this little appliance in position, trace on the watch-plate two lines indicating the directions of the sides of the groove as well as lines fixing its length. Now place the plate in the dogs, setting the point of the pump-center anywhere on the line drawn along the middle of the groove. Turn the plate so that this line is horizontal, and fix it in any way that is convenient.

The arbor C carries a revolving cutter _k_, which can be changed as desired, and is held in position by the clamping screw _d_. Assume that the diameter of this cutter corresponds exactly with that of the required groove; advance it towards the plate, turning the wheel rapidly, the cord being round the ferrule _b_; a circular sink will thus be formed in the plate of the same diameter as _k_.

When this has been cut to a sufficient depth, the tool is moved parallel to the face-plate, and the cutter _k_, continuing its movement of rotation, will now cut, not with its extremity _i_, but with its sides. It will thus form a straight groove of any desired length.

=368.= The cutter is a three-sided prism, or it may have four sides with four cutting edges on the sides, and only one cutting edge at the extremity _i_. If it is preferred to retain only the two acting edges that start from either end of the cutting edge _i_, they may be made more acute, and the other pair reduced by means of a file.

[Illustration: _Fig. 172._]

=369.= _Second method._ This is simpler than the one just considered. At the end of a rod G, Fig. 172, which takes the place of the cutter in the slide-rest, a plate _p_ is fixed. A line is drawn across the face of this plate in such a position that, when G is clamped in the tool-holder, this line is horizontal, and in the plane that contains the axis of the pump-center.

Let it be required to cut a straight groove in the piece of brass _l_. Wax it to the plate _p_ so that the axis of the required groove is over the line traced on the plate. Now fix G in the tool-holder and replace the pump-center by a rod D, the extremity of which is formed into a cutter of a diameter equal to the width of the required groove; the rod D should be fixed in the hollow arbor by a screw. It is then only necessary to set the cutter in motion, forcing the piece _l_ against the revolving cutter, until the requisite depth is attained. Then, by making the tool-holder travel parallel to the face-plate, the groove will be elongated until of the desired length.

=370.= The cutter may be of the form shown in Fig. 171, or it may be as shown at _b_ in Fig. 172, since the movement is always in the same direction. The cutting edges are each formed by two small inclined faces, one pair of which is shown at _b_; they occupy half the diameter of the cutter. At the back of this pair the cutter presents the appearance of the lower half shown in the figure and _vice versa_.

It will be evident that the two sides of this cutter will act while its motion is continuous in one direction.

Besides the numerous operations that can be performed on the lathe as we have hitherto indicated, it may be employed, if divided on the head stock, for tracing out angles, marking the crossings of a wheel, a balance, etc., and for other purposes, many of which are referred to in the course of this work.

PRODUCTION OF SCREW THREADS.

SCREW PLATES AND TAPS.

=371.= The lathes employed in the manufacture of screws are of two kinds; those intended for polishing and, where necessary, modifying the form of screw-heads, much used by watch examiners and repairers, and those specially designed for cutting the threads, which are mainly in use in factories.

Before discussing them, however, we will give some account of the screw-plates and taps in ordinary use.

=372.= =Common Hand Screw-plates.= The use of these is much facilitated by providing a second plate perforated with holes of such sizes that a spindle which just passes into a hole of any given number will be of the size most convenient for forming a screw in the hole of the same number in the screw-plate. For a long time we have made use of two Latard screw-plates so made that a rod which would enter one hole without play was of the most convenient size for forming a screw in the next smaller hole but one (thus the plate perforated with plain holes can be replaced by a second screw-plate, or by using the successively larger holes on a single plate as gauges).

[Illustration: _Fig. 173._]

In order to form a screw that is clean-cut and even, with the least possible straining of the metal, the holes in the screw-plate should have notches cut as shown at F, Fig. 173; they should be carefully hardened and well polished on each side of the notch, and this system is now even applied in the case of the smallest jewel screws.

=373.= =Screw Dies.= The ordinary plate, in which notches are not cut at the sides, squeezes up and strains the metal. This effect is less marked when separate dies are used, and disappears entirely if only a small quantity of metal is removed at a time, and the cutting edges of the dies are smooth and in good order. In addition to possessing other advantages, this form of screw-plate enables us to obtain at will screws of the same thread and different diameters or of the same diameter and different threads. The dies must be carefully fitted to the slides that receive them. Dies cannot be employed for cutting very small screws.

=374.= =Fine-threaded Screw-plates.= At the present day these can always be obtained at the material stores; but thirty years ago it was not so, and the watchmaker was obliged to make them for himself. The following method was adopted:

Take a screw formed with an ordinary plate, in which the thread is broad as compared with the hollow. If the screw does not satisfy this condition it must be modified thus:

Having ascertained that it runs true, and that it is larger than will be ultimately required, insert it in a chuck in your lathe. The T-rest must carry a smooth horizontal rod of hardened steel.

Rotating the screw, hold a slitting file in the hollow; the file should fit into this hollow accurately, and should be smoothed on its two sides, only cutting with one edge. The bar of hardened steel will determine the depth to which the file is allowed to cut. By this means a screw is obtained that has a thread thick at the bottom. With the graver remove the top of this thread, round off its corners, and harden the screw, filing three facets along its entire length, that make it taper.

The tap, having been thus prepared, is employed for cutting a thread in a piece of steel, not too thick, that has been previously annealed, and in which a hole is drilled of the proper size. The thread of this internal screw will be thin and the hollow proportionately broad.

The plate is now hammered cold with care until the thickness is so far diminished that the thread and hollow are as nearly as possible of equal thickness. Harden it and chamfer the ends of the hole with a conical steel point and oilstone dust. Then clean it and cut a thread on a piece of soft steel which may be formed into a tap.

If the operation has been properly conducted, this tap will satisfy the prescribed conditions, and, when hardened, it is to be employed to cut a thread in a second steel plate, which will be employed as a screw-plate; for that first formed must, in consequence of the hammering to which it was subjected, present irregularities in the hole, and can only be used to cut one or two taps cautiously. It is useless for making screws or tapping brass. (See also =378.=)

=375.= _To Clear a Stopped Hole in a Screw-Plate._ Drill a hole through the center of the piece of metal that fills up the hole, taking care to maintain it central, and to employ a drill that is sufficiently small to avoid all risk of contact with the screw threads. Pass a

broach through this hole and, after tightening it with a few gentle blows with the hammer, turn it in such a direction that it tends to unscrew the broken screw, which will in nearly every case, be removed without difficulty by this means.

TAPS.

=376.= Screw-cutting comprises two distinct operations—the formation of a spiral thread on the circumference of a cylindrical spindle, and of a spiral groove within a cylindrical hole to receive this thread.

Taps are made either by means of a screw-plate or in the lathe; we shall presently refer to this second method. Every watchmaker may be supposed to have received, early in his career, instruction as to the cutting of a tap with a screw-plate. Great caution is necessary in the hardening, for if the tap is not true or the metal burnt it will cut badly and be apt to break. Taps are cleaned after hardening with a piece of wood in the lathe or between two hard pieces of pith covered with oilstone dust, and either three or four cutting facets may be made. It is important to avoid the production of a burr in making these facets; a good plan is to make them while the metal is still soft, and to pass the tap through the plate subsequently, as a sharp cutting edge is thereby produced. The facets should be carefully smoothed, and the use of coarse rouge is an advantage.

A tap with three facets gives the cleanest cut and leaves the most space to receive the metal that is removed, but with four facets the roundness of the hole is more certain to be maintained.

[Illustration: _Fig. 174._]

We have seen taps formed as represented at M, Fig. 174, so that the object in which a thread is being cut is loose at the part _o_, when the direction of movement of the tap is reversed. They are also at times made semi-cylindrical, as at G, and work well in the lathe for tapping brass, but we have not tried this form with steel.

=377.= =To Cut a Tap when of Considerable Length.= The following precautions must be observed in order to ensure that a long screw shall be both round and true.

The steel must be of very goad quality, and loose dies should be used in preference to a screw-plate. It is a good practice to employ two pairs of dies (or even more); one to rough out the screw, leaving the thread somewhat larger than it will finally be, and the other to finish after having trued it, and even sometimes lightly turned the surface in places. Very little metal must be removed at a time, the dies should have sharp cutting edges, and a rather large number of threads.

A screw can be made in the ordinary manner in a screw-plate rather larger than is required, then reduced to the requisite diameter, and finished with a plate in which the holes are of the form shown at F, Fig. 173, or in a screw-cutting lathe; in either case, however, care must be taken to avoid straining the metal in its passage through the first plate, on account of the tendency which it then possesses to become distorted in the hardening.

If a micrometer screw is required, that is, a screw of absolutely uniform pitch, it is necessary to apply to makers of astronomical and other similar instruments of precision.

[Illustration: _Fig. 175._]

=378.= =To Cut a Screw of any Desired Pitch and Diameter.= Let it be required to cut a thread on the stem B, Fig. 175, of any pre-determined pitch that already exists in a screw-plate. Turn down the portion _d_ to such a diameter that a screw can be cut on it in this hole, and fit two runners to the lathe of the form shown at G and H. The end of H is drilled and tapped so that _d_ turns freely in it, and a hole is drilled in G to receive the stem B freely, but without sensible play, and a fine notch is cut at _a_.

It will be obvious that if now the ferrule _r_ is caused to rotate, while a fine saw or file is inserted in the notch _a_, a screw will be formed on B of the same pitch as that on _d_, although there may at the same time be a very considerable difference in their diameters. This method may be adopted in place of that explained in article =374= for obtaining a fine-threaded screw.

=379.= =Left-handed Screw Taps.= The manner in which these are made in the screw-cutting lathe will be subsequently explained; in its absence the watchmaker may adopt one of the following methods:

[Illustration: _Fig. 176._]

First method. If, when an internal screw has been cut with a right-handed tap, B, Fig. 176, it be required to tap a second hole in the reverse direction, the following plan may be resorted to:

File the original tap B on two opposite sides, so as to give it the flattened shape shown at A in the same figure. Insert the end into the hole to be tapped and turn the tap to the left with the application of considerable pressure, so as to force the tap to bite. When the tap has been passed in and withdrawn there will be found to be a left-handed thread cut in the hole. For, if the tap is turned towards the right, the thread _f_ passes into the groove already formed by the thread _a_; but, if turned towards the left, _f_ will originate a groove into which _b_ will pass, traveling in an inverse direction to that previously given to it.

The finer the thread of the screw, the better is the chance of success, and with a wide thread it is often necessary to recommence two or three times. If a plate or pair of dies be cut in this manner and hardened, they will serve to cut an even left-handed tap.

[Illustration: _Fig. 177._]

Second method. Attach a comb to one or two sides of a cylinder, as indicated at F, Fig. 177. This can be used to cut a thread in the piece of metal S, that is either right or left-handed according to the direction of rotation of F, sufficient pressure being at the same time applied to force it into the plate. The pitch of the thread will depend on the amount of pressure applied. This plan is only a modification of the one described above, and, as in that case, success can only be guaranteed when a means is adopted for securing a definite relative amount of motion in F around its axis and S vertically.

[Illustration: _Fig. 178._]

Third method. A tap of unhardened steel is filed into a triangular form, C, Fig. 178, and twisted so as to bring the angles _b_, _f_, towards _a_, _d_, etc.; we thus obtain a tap which will serve, throughout a certain portion of its length, to cut a left-handed thread, but the part that is not so adapted, at the extremities, will require to be removed before hardening.

[Illustration: _Fig. 179._]

=380.= _To Make a Left-handed Tap by Means of a Right-handed Tap._ A portion of the right-handed tap is filed off on three faces to the section shown at _b_, Fig. 179, and firmly set in the die _d_ so as to be held in the frame for screw-cutting dies. A second die, _f_ made of brass and having a semi-cylindrical recess opposite _b_ is fitted to the frame. The diameter of this semi-cylinder should be the same as that of the rod on which a left-handed thread is to be cut. Now grip this rod as shown at _a_ by means of the screw _g_, so that it is held between the die _f_ and the block _b_, and rotate the frame or the rod _a_ towards the left; a spiral groove will thus be cut by the thread on _b_. It is sometimes an advantage to cut this thread lengthwise in the manner indicated at _b′_.

[Illustration: _Fig. 180._]

This method enables us to cut a given thread on a rod of any given diameter. From an examination of Figs. 179 and 180, it will be seen that a simple comb of the form of C or D, carefully made by hand and fixed in the place of _b_, can be employed to cut a right or left-handed thread on any given rod; it is advisable, however, that the teeth of the comb be inclined to the axis of the screw, like the thread of an ordinary tap, as otherwise the operation becomes more difficult and success less certain.

[Illustration: _Fig. 181._]

The method may be simplified by taking a brass plate, D, Fig. 181, of sufficient thickness, and firmly setting in it the right-handed tap, _v_, having only filed away two opposite faces before hardening. The rod to be tapped is then introduced with considerable pressure into the hole _j_, and, if rotated towards the left, it will receive a left-handed thread of the same pitch. The notch shown at _b′_, Fig. 179, will facilitate the operation, as a cutting action will take the place of compression.

=381.= M. Gontard has suggested a modification of this arrangement, which consists in forming the die _f_, Fig. 179, so that the original right-handed tap can be embedded in a hole previously tapped in it and filed away on the side towards _b_ so as to expose a cutting edge; and he points out that, by suitably inclining the frame with reference to the axis of the rod to be tapped, the appliance can be used to cut a double or even a triple-threaded screw, right or left-handed. He further draws attention to the fact that in a screw formed in this manner the sides of the thread are smooth and polished, a condition which cannot be secured when either a plate or dies are used.

=382.= =To Increase the Diameter of a Tap.= It sometimes happens that a screw will not penetrate to a sufficient depth, or fits too tightly into its hole, owing to the tap employed being of a less diameter, either in consequence of the hardening, polishing or wear, or through having been formed in a different screw-plate. In such a case the following expedient may be resorted to:

[Illustration: _Fig. 182._]

Make a fresh tap in soft steel and file away two opposite sides so as to give it the section shown at A or B, Fig. 182: after measuring the diameter at several points in its length, hammer gently on the flattened sides. With a little care and by using a micrometer at intervals for testing the alteration in diameter, it will be found that the required increase can be obtained without much difficulty. The tap is then hardened and polished, etc.; indeed, it is best to make a fresh tap.

METHODS OF TAPPING HOLES.

=383.= It is needless to refer to the method of tapping by hand, as it is well known to all practical men.

=384.= =Tapping in the Lathe.= The plate of a watch is gripped in the dogs of a face-plate, the hole to be tapped being centered by means of the pump-center, which is then withdrawn, and a tap held to the hole; the face-plate is then caused to rotate either by the hand resting on its circumference, a slight backward motion being given after each advance, or the motion may be continuous and be given by the wheel. In the latter case, however, the tap must have a good cutting edge and only be held in the hand with the degree of force required to make it cut, so that it may rotate without breaking in case the resistance opposed becomes too great. The tap may be steadied on the T-rest.

=385.= =To Tap with a Mainspring Winder.= The ordinary mainspring winder will, if the click work is removed, be found very convenient for tapping holes, and indeed, for forming the external thread on screws. Having removed the winding arbor, replace it by a tap carefully centered; then introduce its coned end into the hole in the plate, which must be pressed forward while the handle is turned, a short backward motion being given to it at frequent intervals. When the tap is engaged sufficiently in the hole it is merely necessary to maintain the plate at right angles without applying pressure.

=386.= =To Tap with a Bow.= Instead of the mainspring winder, one of the small drill-stocks to be driven by a bow, consisting of an arbor, with a coned hole at one end and ferrule at the other, supported in a frame that is clamped in the vise, may be used. They are to be obtained at any tool-shop.

The bow being on the ferrule and the tap properly centered in the arbor, the hole is held against the coned end and the bow worked with an alternate forward and backward movement; but if the tap has a good cutting edge and the bow is strong (of steel or cane), a hole may be tapped with a single stroke of the bow. After a few trials the method will be found very easy and certain.

A regular and rather slow motion should be given to the bow, which should be long and strong. It is well to ascertain the number of revolutions of the ferrule that correspond to a stroke of the bow, so as to ensure that the tap is not introduced to a greater depth than is required. If it is desired that the screw work easily in the hole, the tap should be moved several times backwards and forwards.

=387.= The little turns here referred to, some of which are perforated throughout their entire length and others only at one end, are very cheap and will often be found useful; they can be adapted to receive drills, broaches, taps, etc.

=388.= =To Tap in an Ordinary Lathe.= In factories it is a common practice to tap the holes in plates, etc., and even to cut the threads of screws in a lathe specially arranged for the purpose. The tools adapted for such work are of two kinds: in some the tap enters to the required depth, when it is immediately arrested, disconnected, and then rotated in an opposite direction; in others, the tap advances to a definite point, and is immediately withdrawn. As a rule, however, the tap remains stationary and the object is caused to rotate.

=389.= =Beillard Lathe for Tapping Screws.= The axis F M, Fig. 183, is perforated throughout its length. At F, the screw-plate G is dovetailed into it. The inner end of the hole in this plate is slightly coned to facilitate the insertion of the brass wire D, and it must be exactly in the axis of F M. A guide B sliding on two rods _c_, _c_, is traversed by the rod D which can be clamped in it by the screw _a_.

By pushing D against the screw-plate at the same time that the handle N is rotated, a thread will be traced on it and it will emerge at _k_. When B has advanced to the point _m_, the screw _a_ is released, B is drawn back, and _a_ again clamped.

[Illustration: _Fig. 183._]

When a long screw, such as X _x_ has to be tapped, the screw-plate is fixed at _m_, and the guide B is fastened on to the portion X. Of course the hole in the screw-plate must always be abundantly provided with oil.

If the screw-plate F is replaced by a plate perforated with a round or square hole, a drill, broach or tap may be substituted for _k_, being clamped by the screw _h_, and the tool is at once available for drilling, broaching or tapping any given hole.

RAPID MODE OF MAKING A SCREW.

=390.= The methods ordinarily adopted by watchmakers are too well known to need description; we will therefore at once proceed to give a special plan recommended by M. Vissiere.

An eccentric poppet-head with boring-plate, Fig. 185, is fitted to the bed of the lathe, the eccentricity being such that the axis of the centers is at the point _a_ on the circumference of the circle _a y_. The conical hole, having a center at _a_, is cut away towards the rim of the plate to the degree indicated in the figure, and its center is so placed that the vertical line _f_ and the radius _d_ are inclined at 120°. The position of the T-rest is shown at _s_, and by bringing it into actual contact with the disc the steadiness of both is increased.

The fixed headstock of the lathe is provided with a runner of the form B, Fig. 184, terminating in a point _m_ at one end and a hollow cone or funnel _n_ at the other end.

Having filed the ends of a rod T, of any required diameter, square and fitted a ferrule, support it between the two cones, _a_ of the boring-plate and _n_ of the runner. Near the end _a_ cut a hollow _r_ sufficiently small to allow the stem to pass through the notch in the hole _a_, Fig. 185. After passing it through, the rod will be supported as shown at H, Fig. 184, so that the rim _e i_ rests against the cone.

[Illustration: _Fig. 184._]

[Illustration: _Fig. 185._]

Further explanation is hardly necessary; after removing the portion _c g_ with a graver, turn down to a point _p_. When making a screw, turn out a second hollow _o o′_; it then only remains to turn off the disc at the extremity, and the screw will be roughed out of the form _c p g v_.

If it is preferred to work with a point at the left-hand end of B, remove the rod after the point _v_ has been turned, replace _m_ B _n_ by a common runner, reverse B, and recommence the operation.

It would be difficult to devise a method for roughing out a screw and making a point that would be more expeditious than the one here described.

SCREW-HEAD TOOLS.

=391.= These are of various kinds: some work by hand and others by a bow. The jaws are brought together sometimes by a sliding ring, and at others by a milled head placed between them and rigidly attached to a pin tapped with right and left-handed threads that engage in the jaws. But neither of these plans is good; the screws are not held firmly and they are rarely well centered; owing to the slight displacements of the jaws.

[Illustration: _Fig. 186._]

A better plan is to arrange, either in the lathe or in the jaws of the screw-head tool (when driven by a bow), a series of chucks of the form shown at T, Fig. 186. They are easily made and tapped, the hole _i_ serving to remove the metal from the inner end of the hole that has to be tapped; such chucks occupy very little space, and, if numbered to correspond with the size of screw, any chuck required can be found without trouble. If the hole becomes too large owing to frequent use, a larger size of tap can be passed through the hole and its number changed.

=392.= A set of such chucks is almost indispensable at the present day to the watchmaker who wishes to repair watches well; for he rarely makes his own screws, as they are to be obtained well made and very cheap at the material dealers, whereby a great saving of time is effected. But their heads are seldom of the proper size to fit the original sinks, and by being provided with such a series of chucks the watchmaker can at once overcome this difficulty, as he can turn the heads down with a graver.

=393.= R, Fig. 187, is an arbor for a screw-head tool that is driven by a bow, and is adapted to receive such chucks, or it can be used in an ordinary lathe, _d_ being supported on a pointed center, and _g_ in a boring-plate, Fig. 188, or in a cone-plate center.

=394.= In this form of screw-head tool the portion A is sometimes perfectly cylindrical, so that the piece V can slide on to it, being clamped by the screw _b_.

This tube V is cut away through about half its length with a notch, as indicated in the figure; bent pieces of hardened steel _c_ and _n_ are screwed to either side of the notch. Screws, _h_ and _f_, provided with lock-nuts, determine the distance between these plates, and when V is in position on A the ends of _c_, _n_, will rest on the screw-head, leaving just sufficient space between them for inserting the file that cuts the slit.

[Illustration: _Fig. 187._]

Hard steel caps of the form shown at M may also be fitted to A, a notch being cut in them to receive the screw _b_. These will be found useful as guides for filing or polishing screw-heads, or the ends of arbors flat, reducing the heads of several screws to the same height, etc.

[Illustration: _Fig. 188._]

=395.= The tool for forming the U-spaces in a cylinder escape-wheel can be easily be converted into a screw-head tool with laps. A glance at Fig. 189 will at once make this evident. A number of chucks are adapted to the arbor A, and in the tube _c c_ either a T-rest or a spindle carrying a lap is fixed.

It will also serve as a tool for drilling; a drill-chuck with drill, _f_, being adapted to A, and the object to be perforated at _b_ resting against a plate that projects at right angles from a slide _d d_, which may be advanced by a screw _g_.

=396.= The modern watchmaker has so little call to cut screws that it does not pay him to purchase a screw-cutting lathe; for a very small sum he can have screws of any thread or diameter cut by those who make a specialty of such work, always provided that he cannot find what is wanted in the material stores. The same thing also applies to fuzees.

[Illustration: _Fig. 189._]

TOOLS FOR CUTTING AND ROUNDING-UP THE TEETH OF WHEELS.

WHEEL-CUTTING ENGINE.

=397.= The machine for dividing the circumference of a wheel, termed the wheel-cutting engine, and one form of which is shown in Fig. 190, is well known to nearly all workmen. The wheel is fixed to a chuck at B by wax or screws, or by the pressure of a hollow cone or “sugar loaf” of steel, to the apex of which pressure is applied by the arm D, or in other ways. The wheel may be centered either by a pump-center within the chuck or by an appliance such as is shown in Fig. 191, except that the arm _b_ is curved and its index much longer. This little addition may be fixed to the frame of the engine in any convenient position.

[Illustration: _Fig. 190._]

The chuck B that carries the wheel is rigidly connected with a large brass plate A A, on which are concentric circles of divisions, and the whole can be maintained stationary by setting the point of the index C C in any desired hole on the division-plate. The cutter is carried on an arbor (shown separate at L) between horizontal bearings in the frame J, and is caused to revolve by means of the pulley K. The several parts lettered E, F, G, H, are for bringing the cutter against the wheel and modifying the direction in which it moves, so that the machine can cut straight or inclined teeth, bevel or crown wheels, etc. It should be added that the engine here represented is more complex than those ordinarily used for cutting watch wheels, although the principle on which it acts is the same.

The teeth may be cut by circular cutters of the nature of files, by a small straight cutter, similar to those used in a slide-rest projecting from a rotating axis, or by several such cutters mounted on a disc which is caused to rotate. For the sake of distinction it will be well to refer to the first of these as _file_ or _mill cutters_, while the second and third may be termed respectively _single_ and _multiple blade_ or _composite cutters_.

[Illustration: _Fig. 191._]

Watchmakers rarely possess a sufficiently large assortment of file-cutters for making all the various forms of teeth that are met with in horology; but this deficiency can be supplied by making them for themselves to any required pattern in the manner subsequently described.

=398.= _Observations._ The wheel-cutting engine in which the plate is caused to rotate by means of a tangent screw is usually the most accurate. If the pitch of the screw is fine it will give all the subdivisions of a circle that are required for ordinary work, but it is essential that a good form of counter be attached to the screw, and a certain amount of calculation is always needful.

The engine that has a division-plate with conical holes arranged concentrically over its surface is simpler and better adapted for rapid work. The larger this plate, the greater is its chance of being correct and, at the same time, it affords room for a larger number of divisions.

It is preferable that the cutter frame rise and fall in a vertical dovetail, for when the arbor is carried in an H shaped arm pivoted on two screws, the teeth are always slightly dished. The entire apparatus should be somewhat heavily constructed and supported on a solid bed; so as to prevent the vibration of the cutter-arbor from being distributed over the entire machine.

The highest numbers on the plate should be used whenever it is possible, so as to diminish the error due to irregularities in the sub-division. For example, in cutting a wheel of 30 teeth, use the 90 or 120 circles, taking every third or fourth hole.

These remarks will probably be sufficient to enable any watchmaker who possesses a wheel-cutting engine to employ it with success; we will, however, add the description of a few appliances or processes that have a bearing on this question.

=399.= =To Divide a Wheel so that it has one Tooth more or less than any given number on the Division-plate.= It is to be observed that neither this nor the following method is mathematically exact, but if it is practiced with care and the division-plate is of sufficient diameter, the error may as a rule be neglected.

[Illustration: _Fig. 192._]

Let P, Fig. 192, be a division plate that has a 30 circle, but not one of 29 or 31 divisions. Divide the circumference of a disc _d_, seen on edge, into a large number of parts in the engine, 360 for example, and fix it to the end of the index, at the same time attaching a finger, _i_, to the support _s_. Now advance the screw of the index through a distance corresponding to the angle _l_ P _k_ included between the two successive points of the 30-division circle. To measure this distance a pointer should be previously fixed to the frame to correspond with the middle point of a hole in the circle under consideration, and the motion should be arrested when it coincides with the next succeeding hole. Assume that this amount of displacement has required three complete turns of the screw; 1,080 divisions on the disc have thus passed under the finger _i_. Dividing this number by 31, we obtain 34.83.

After observing the division on _d_ that coincides with the pointer _i_, cut the first space of the wheel; then cause 34.83 divisions to pass under _i_, in such a direction that the plate is drawn with the arrow, and transfer the index to the next hole of the circle, rotating this time opposite to the arrow; the second space can now be cut, and so on.

With a view to diminish errors arising from the omission of fractions, since 31 does not divide evenly into 360, a number of multiples of the number 34.83 should be determined. Thus 4 times 34.83 is 139.32, so that, when the fourth space is cut, the pointer _i_ must be at this number of divisions from its initial position.

The index should be so situated that, when half the arc _l k_ has been traversed, as explained above, _s a_ is at right angles to the radius P _r_ of the division-plate. If it is desired to move _d_ in a reverse direction, it must be moved backwards to a considerable distance and then forward up to the required point so as to avoid error due to backlash. The screw of the index should fit the support s firmly and without any shake.

=400.= =To Cut a Wheel with any Given Number of Teeth.= When the given number does not occur on the division plate, proceed as follows: Take a strip of metal, for example a pliant piece of soft steel, and cut in it a series of equal and equidistant notches as shown at B, Fig. 193. Cut the band to such a length that it has the same number of pairs of teeth and spaces as the wheel is required to have teeth. Now turn a lead disc of a diameter that the strip of metal will exactly enclose; fix this strip round the circumference with pins, screws, or in any convenient manner, as is shown at C. We thus obtain a temporary division plate which can replace the permanent one or be attached to its upper or under surface, and, when an index has been adapted to it, the wheel can be divided into the requisite number of parts.

[Illustration: _Fig. 193._]

When employing an engine the division plate of which is worked by a tangent screw, the above affords an easy means of making the divided head for the screw with any desired number of divisions.

=401.= With a view to insure accuracy, it is advisable to employ a disc of large diameter as the errors of division are thereby rendered less important and the metallic blade can be made to lie closer to the rim.

The blade is subdivided by a saw to which a guide is attached as indicated at H, Fig. 193, or the saw can with advantage be replaced by a file that only cuts on its edge and not on either face, or by a pair of mills or revolving cutters united together as shown at S. The following plan, however, appears to be more expeditious and to involve less trouble to ensure accuracy.

[Illustration: _Fig. 194._]

A hole _a_, Fig. 194 is drilled in a metallic band by means of a semi-cylindrical drill fixed in the chuck of a lathe or in a wheel-cutting engine, etc. It will be convenient if the drill can be set vertical. Beneath it is a brass bed-plate in which are fixed two pins equal in diameter to the hole _a_; this hole having been placed over one pin _b_, the band is held firmly against the other, while the second hole is drilled. This is then transferred to the pin, and so on.

In the absence of a suitable tool, a well made measure can be employed for marking a series of points with the aid of an eyeglass; the holes are then drilled with the bow or in any other manner.

=402.= =To Cut a Wheel, Ratchet or Pinion on an Ordinary Lathe.= When only a moderate degree of accuracy is required, the ordinary lathe can be adapted for cutting the teeth of minute wheels, ratchets, pinions, etc., by making the following appliance:

The piece B, Fig. 195, provided with a stud at _p_, slides on two horizontal and parallel cylindrical rods fixed to the slide C, or it may move in a dovetail. The cannon _d_, carrying a ferrule _k_ and a file-cutter _f_, rotates on the foot at _p_ without shake; and the cord of a wheel or bow passes round _k_.

[Illustration: _Fig. 195._]

R, the wheel to be cut, is supported between the runners, the divided plate V, which may even be an old wheel with the required number of teeth, being fixed to the axis of R. V is held stationary during the operation of cutting, by the index _l_. The mode of action hardly requires explanation: while _f_ is rotating, advance B until it is arrested by the stop _t_; then draw B back, advance _l_ to the next division on the plate, and so on.

=403.= We have said enough on this subject to enable any watchmaker to make such a tool, modifying it or completing it according to his requirements. We would only remark that: (1) If a cannon of the form _d_ is used, the stud should be diminished in diameter at its middle part for about three-quarters of its length, so that friction occurs only at extremities; and (2) if a wheel is used to rotate _k_, there should be an idle pulley at _m_ supported on a fixed arm independent of B, either attached to the lathe-bed or bench, or fixed in the vise, so that the ferrule _k_ can move backwards or forwards without altering the tension of the cord, in the manner indicated at Y.

=404.= =Wheel-cutting Arbor-chucks.= These appliances are specially useful in making wheels that are required to be rigorously true, such, for example, as escape wheels. The form is represented in Fig. 196.

It is simply the arbor of an ordinary lathe, formed in two pieces, _b a_ and _b c_, the body _b d_ being very accurately fitted into the conical hole in the plate of the wheel-cutting engine. If now a wheel is fixed with wax on the extremity _z_ and turned in the lathe to the required form, it is only necessary to unscrew _b c_ and introduce _b d_ into the socket of the wheel-cutting engine; then

having cut the teeth, the piece _b c_ is replaced, and the whole is set in the lathe, if required to test its truth, without the wheel having been displaced from the chuck.

[Illustration: _Fig. 196._]

It will, of course, be evident that the two parts must be accurately fitted together; the tapped hole and the screw must be true with the axis. M. Millot, with whom we have seen this form of arbor in use, has not been able to detect any eccentricity, although he often employs them.

=405.= They might be formed in one piece, as _a d b_, with a point at _p_. A boxwood ferrule is then fitted onto the portion _b d_, where it is clamped by two screws, and these can be released when it is desired to insert the chuck into the wheel-cutting engine. The points of these screws should be received in recesses in order to avoid the production of any roughness on the surface of _b d_.

Wheel-cutting engines have been made to receive these arbor-chucks without removing the pulley. The point _c_ is placed in a hole and the upper end is enclosed in a collar, which is tightened by means of a screw.

The arbor used by M. Millot had a lantern chuck, and this is very convenient in making objects that require to be measured during the progress of the work.

=406.= =Modification of the Ordinary Arrangement for Holding the Wheel While Cutting.= In the wheel-cutting engine as usually met with, the wheel (when not mounted on an axis) is held against the chuck by a hollow steel cone, on which presses an arm that slides on a vertical pillar and can be clamped in any position. The hole at the end of this arm does not always, therefore, correspond with the point of the cone, and, as a consequence, the wheel often gets displaced during cutting. This inconvenience can be avoided by adopting the following device, which we have seen in use with several watchmakers.

[Illustration: _Fig. 197._]

The pillar with its sliding arm is replaced by an iron or steel piece of the form G, Fig. 197. The point _a_ is received by the central hole at the lower end of the division-plate axis, while the screw _b_ presses on the point of the cone, clamping it firmly. Further explanation seems unnecessary; we would only add that the piece G must be made strong and perfectly rigid.

CUTTERS FOR FORMING THE TEETH OF BRASS WHEELS.

=407.= For making the teeth of the wheels of a train, a special form of cutter, set to revolve on an axis, is employed, and it may be constructed on either of three distinct systems.

[Illustration: _Fig. 198._]

[Illustration: _Fig. 199._]

(1) A single cutter mounted on an arbor, as at A, B, Figs. 198 and 199; this may be termed a _single cutter_.

(2) A circular cutter, formed of a series of such single cutters, which will be termed a _multiple blade_ or _composite cutter_. Two specimens are shown at F, J, Fig. 200.

[Illustration: _Fig. 200._]

(3) The pinion, or steel wheel cutter or mill, formed of a single piece of metal, as seen in Figs. 201, 202 and 203. These may be described as _mill_ or _file cutters_.

=408.= =To Make a Single Cutter.= The form shown at A, Fig. 198, is roughed out to as nearly as possible the required form in good steel. Some makers, possessed of exceptional skill, make them entirely by hand, and they make very beautiful teeth by this means; but as a rule watchmakers cannot look for such success, so that it is better to complete the formation of the cutter in a specially arranged tool.

[Illustration: _Fig. 201._]

[Illustration: _Fig. 202._]

The two sides may be made in the wheel-cutting engine, with the same mill cutter, which is inclined when used to undercut the acting edge; but this operation is not as easy as it appears at first sight, and the watchmaker will find it to his advantage to make the following device:

[Illustration: _Fig. 203._]

A spindle, _b d_, Fig. 204, supported between the runners, _t_, _v_, serves as an axis for the arm _f g h_, which is bent at _g_ so as to afford a support to a conical cutter _a_, driven on the ferrule _c_. The descent of this arm is limited by an adjustable stop, fixed to the bed of the turns.

Having removed the T-rest, replace it by the rod N, to which the cutter is clamped by a screw _k_, after being roughed out so as to reduce the work required of the cutter.

Place N so that the conical cutter occupies the position indicated at _z_, and, if a slight pressure be applied at _h_ while _a_ is caused to revolve, both the straight and curved portion of the side will be formed, and the side will, at the same time, be bevelled to an angle corresponding with that of the cone. The curved portion of the side will be more or less undercut, according as the arm _h_ is depressed below the horizontal plane passing through the axis of the lathe. The opposite side is formed by inverting the piece _f g h_.

[Illustration: _Fig. 204._]

In smoothing or polishing it is only requisite to replace the cutter by a smooth conical roller, and to work as before.

=409.= The cutter is sometimes fixed in the arbor as shown in Fig. 198. The arbor itself is thick and perforated with a round hole in which the tail of the cutter accurately fits, a slight pressure applied by the screw _m_ being sufficient to make it steady.

For cutting the escape-wheels of clocks the arbor should have a velocity of about 200 turns a second.

M. Peupin, a skilful watchmaker who adopts the practice here given, having observed that with a sharp cutting edge he did not obtain a sufficiently smooth surface, succeeded in obviating the difficulty by drawing a polisher with rouge along the cutting edge, maintaining it at right angles to the plane of the cutter. This operation, if carefully executed, will serve to remove the feather-edge, to make the edge even and yet not dull, and to secure a highly polished cut surface. The sides of the teeth will present a proportionately better surface, according as the portion _c a_ (M, Fig. 198,) approximates towards the dotted line _c d_.

His escape-wheel teeth are cut in successive stages. The last stroke of the cutter is given by advancing it against the side of the wheel, so that the cutter axis remains in the plane of the wheel.

=410.= =Triangular Cutters.= When a cylindrical or conical mill is not available for finishing and sloping the sides of a cutter, it may be replaced by a triangular cutter (T or C, Fig. 205,) and when the application of much force is required there may be a pointed bearing; but this is seldom necessary.

[Illustration: _Fig. 205._]

If carefully hardened and set, such a cutter gives a clean cut; of course it will not act for as long a period as the conical form above described, but this is of comparatively little importance, since the blank cutters are always roughed out previously to nearly the requisite shape.

=411.= =To Make Several Cutters at Once.= By adopting the following method, it is possible to make several such cutters in one operation.

Turn a steel disc of the form of an ordinary mill cutter, as shown at _l p_, Fig. 200. To finish it, giving the same curvature to the two sides, take a piece of steel, C, and shape the corner _r_ to exactly correspond with the side of the point or ogive of a tooth, bevelling it so as to give a cutting edge at the upper surface; then harden and smooth it with care. Having fixed it in position in the tool that carries the arbor _a_ and the roughed out disc (whether this be the lathe, wheel or pinion-cutting engine, or a special device) in the required position, one side of the disc may be finished. The arbor _a_ is then reversed and the other side finished in the same manner, so that both sides have the same curvature in opposite directions.

Of course the tool C may be advanced against _l p_, either sideways from _r_ towards _l_, or radially in the direction _l p_, as is most convenient. Or the tool might remain fixed and the disc advance against it radially or laterally.

The traverse slide in a lathe is usually provided with a stop; it would then be very easy to form one side of the disc in such a tool, afterwards reversing the arbor and forming the other side.

If a very good cutting edge is desired, the sides should be smoothed and, when the disc is completed, it may be divided into pieces similar to B, Fig. 199, each of which will serve as a cutter. It will be noticed that the acting edge is not undercut behind; it is thus necessary to slope the cutter a little as shown at B, as otherwise the rim will choke in the spaces of the wheel, straining it without cutting.

=412.= =Composite Cutter Formed of a Succession Of Single Cutters.= By mounting a series of identical single cutters round the circumference of a disc, a circular cutter can be formed in the manner indicated in Fig. 206. The upper portion represents the arrangement of the pieces while they are being turned, and the lower portion shows their positions when the cutter is ready to be used. M. A. Croutte, to whom we are indebted for several of the details here given, was much surprised that this form of cutter is not better known, since it possesses certain special advantages; we will summarize his remarks on the subject.

[Illustration: _Fig. 206._]

The separate cutters _b_, _g_, etc., Fig. 206, are not undercut from the acting edge backward; they are merely reversed, so that this acting edge is towards the front, in other words it lies along the radius. These separate pieces possess a special advantage in that they can be used until the steel is quite worn out by the setting; in this respect differing from the undercut cutters, for they are not altered either in form or thickness by setting.

As a set-off against this important advantage, they are characterized by the inconvenience of requiring that the two sides of the blade be exactly in a plane at right angles to the axis, and that the slide carrying the cutter-arbor shall move in a direction parallel to this plane. And even when this double condition is satisfied, there will be friction of the two sides above the dotted line _i j_, Fig. 199, against the sides of the teeth; and if the above named conditions are not satisfied, the cutter, being presented edgeways, will be choked with brass, and the results will be unsatisfactory.

=413.= In order to ascertain whether such a fault exists, it is only necessary to notice whether the cutter becomes brass-colored on one side towards the point, and on the other more inwards, and the sides of the teeth exhibit striæ or scores in opposite directions, as indicated at E, Fig. 207. The white strip, 1, 1, corresponds to the bottom of a space between two teeth; 2, 2, and 3, 3, the two sides of this space, spread out like an open book.

[Illustration: _Fig. 207._]

By examining the marks with care, and noticing the direction in which they are inclined, it will be possible to ascertain both whether the separate cutters are out of place, and in which direction the arbor should be moved in order to correct any error.

We must, then, repeat that all the cutters must satisfy this condition, because if only one is wrong it will produce the scores here referred to.

The necessity of these precautions in the use of such a composite cutter, and the fact that the friction of the portion above the line _i j_, Fig. 199, renders it difficult to obtain a polished cut (which is essential for such delicate depths as those of watches), have doubtless prevented its use becoming general. For work that is somewhat larger or rough, it will be found to give satisfactory results and will last longer than a single cutter. A lubricant, such as glycerine or oil, should be applied to it.

=414.= =Composite Cutters with the Cutting Edges Undercut.= An old Paris clockmaker, Brisson, used a cutter of the form F, Fig. 200, for the teeth of his wheels. He undercut the two sides of the blades by means of a small special tool. Strictly speaking, the operation can be performed by hand.

In order to ensure that the curves that form the ogives of teeth are alike on the two sides of a cutter, he made a series of templates or standards of the form C, Fig. 206, in which were two holes, C and _c_, of equal diameter. The upper one, which might be funnel-shaped so as to give a cutting edge, was half cut away, and, after being hardened and set, could be used to give a final stroke to the circumference of two discs of equal diameter. These two discs, or one cut through a diameter would suffice, having been brought by a file to the form H, and joined as shown at _r s_, can be mounted eccentrically so as to present a cutting edge to

the roughed out cutter A; the two sides can thus be made even. The disc may then be finished by cutting away the metal so as to give the form shown at F, Fig. 200.

By the aid of the standards he could easily reproduce the same forms of teeth when required.

Fig. 200 comprises, at J, a cutter for the teeth of watch wheels of the form employed successfully by M. A. Phillippe. The figure will explain itself.

We have known a Geneva wheel cutter who employed these composite cutters with advantage in making duplex wheels. The principal difficulty he experienced arose from the distortion of the metal in hardening, because the acting portion naturally lengthened a little. This form of composite cutter certainly demands careful workmanship, but, if the construction, hardening and polishing are good, it will produce fine work and will last a long time.

=415.= =General Observations on Cutting the Teeth of Brass Wheels with a Single or Compound Cutter.= High-class English watches, the movements for which are made at Prescot, in Lancashire, have the wheel teeth made by a composite cutter after the wheels are riveted to their pinions. We have remarked that these watches make less noise when running down than those in which the teeth have been formed with a mill or continuous action cutter.

Success in forming teeth with cutters depends mainly on the securing of a good form as regards the cutting edge, and on its being maintained in good condition; on the steadiness of the entire machine, so as to avoid vibration; on the weight of the wheel, and on the velocity of the cutter being sufficient. A cutter ought never to assume a brassy color except when it requires setting; if it does so, and this is not the case, it proves that the metal is being strained or scraped with friction. The velocity must be very considerable; greater with a single cutter than with one that is composite. The velocity is limited by that point at which the heat generated would cause the oil to evaporate, soften the cutter, distort, and sometimes even displace, the wheel operated on. The engagement of the cutter with the metal must be very slight, and should never be increased suddenly.

Attempts have been made to enclose the arbor bearings in horn, but it is liable to be distorted by the heat.

Before dividing the disc into cutters it is essential that the two edges be carefully smoothed, and this without their being distorted. This can easily be done in an old depthing tool, using an arrangement like that shown in Fig. 208. The lap must be of hard wood, and its right-hand corner rounded off so as to resemble the side of a tooth; it is set to engage with one side of the cutter. We say the right-hand corner, because a lateral pressure can then be applied. It is important that the surface as left by the graver be clean cut, because if the smoothing is too much prolonged, it will deform the cutter.

[Illustration: _Fig. 208._]

=416.= In some factories it is usual to use discs about 2½ inches in diameter, for cutting the teeth of brass wheels in timepieces. The single cutters are arranged round the circumference as follows: One forms a space between two teeth; the one immediately preceding forms the right-hand side of the ogive, and that which follows forms the left-hand side. By adopting such an arrangement of separate cutters, if their side that lies against the disc is slightly inclined backwards it is no longer necessary to bevel off the cutting edge.

MILL CUTTERS FOR STEEL.

=417.= =Pinions, Keyless Wheels, Etc.= The cutters that last for the longest period when used for cutting steel are those formed like a file; but a watchmaker is not always in a position to make them himself; we will, therefore, here only speak of those he can make, the description of the first few being taken from a work by M. A. Phillippe, of Geneva, _Les montres sans clefs_ (keyless watches).

=418.= =Cutter for Forming the Inclined Teeth of Winding Pinions.= Fig. 201 shows at S a section along the axis of such a cutter, and at P a side view. When it is believed to be of the required form, rest a piece of lead on the T-rest of the lathe and press it against the rotating disc. The impression made in the lead will afford a means of ascertaining both whether the form is correct, and whether the surfaces are smooth enough. This last point is important.

The cutting edges are formed by merely making a number of notches around the circumference with a tool for cutting ratchet teeth. Then advance this ratchet cutter so that it may engage with the convex edge of the cutter operated upon, and against the back of

the teeth of this cutter; the ratchet cutter is then in a position to form a second face, _o i_, by which the teeth of the cutter are undercut at the back, but in such a manner that a small flat surface _o a_ is left in order to retain the form. When a cutter made in this way will no longer bite, it may be set by passing a hard slip of whetstone over the faces of the teeth.

The ratchet cutter employed for making this cutter should never be pressed against it heavily.

=419.= =Cutter for Ordinary Wheel Teeth.= We will now pass to the consideration of cutters for forming teeth of the usual shape, of intermediate steel wheels, set-hands wheels, pinions, etc. They may be made as follows:

The rim is indented with small fine ratchet teeth, _b d_, Fig. 202. Any burr produced on the sides is then carefully removed, and the cutter is placed in the wheel-cutting engine, and notches, _c_, _c′_, _c″_, _c‴_, etc., are formed on either side with a flat square-edged cutter of such a thickness that the circumference is about equally divided into hollows and prominences. It is important to note that the right side of the teeth must be but slightly roughed, not more than is required in order to raise a slight burr, all that is necessary to form the cutting edge of this portion of the disc. In roughing these sides, at least one out of every two of the small ratchet teeth on the circumference should be left untouched, so as to ensure the required thickness being maintained.

The cutter shown in section and elevation at S and P, Fig. 201, might be cut on the side _n_ in the manner here explained, and the convex portion _k_ might be indented with a fine ratchet-toothed cutter, carried in the hinged cutter-frame of the wheel-cutting engine. The degree of penetration may be determined by fixing an ivory disc against the cutter and concentric with it, the two differing in diameter by the depth the cuts are to be made. The teeth will be rather too square towards the circumference, but their form can be carefully corrected by hand. It is obvious that the very greatest caution is necessary in hardening cutters.

=420.= =Rose-Cutters or Forming Pinion Cutters.= As the edges of pinion cutters are rounded, they can be made in the manner suggested by Thevenin. Supporting the roughed out cutter in the cutter-frame of a wheel-cutting engine, he fitted in the axis of the division-plate a kind of rose-cutter, N, Fig. 205. Its extremity, _n_, instead of being flat, is hollowed out as indicated by the dotted line, and, by presenting the cutting edge thus obtained endwise to the grooved edge of the cutter, the correct form can be given to it. With a mushroom-headed piece of steel and oilstone dust, the cutting edge of the rose-cutter can be made more or less acute by modifying the angle of this steel lap.

=421.= =Other Forms of Pinion Cutter.= When a cutter is merely required for a special piece of work, and not for continuous use, it will often be sufficient to make it as shown at A, Fig. 203; this is made by grooving the disc (_c_), or forming its edges as at _d_, after which a series of teeth are cut on the periphery with a revolving cutter, taking care to leave no more burr on one side than on the other. Then pass a smooth worn file (or a worn flat cutter) over the faces of the teeth, applying oil at the same time, so as to produce a slight burr on the edges; if the file is not allowed to bite too much and is well managed, these minute ridges will be uniform. After hardening, the cutter is ready for use.

If the faces were smoothed without subsequently applying the file, the cutter would not bite; for its action depends on the slight projection of metal that corresponds to the file-cuts. The cutter is nothing more than a circular file, with two cuts per tooth. If the corners are turned over evenly by means of a very hard burnisher the same effect will be produced; but this operation is delicate, as the amount of metal turned over must be the same in every case.

When a cutter does not bite, it must be softened and restored to its initial condition.

=422.= Or the following method may be adopted when it is required to make a cutter for a special purpose.

Proceed at first in the manner just described, but the periphery is divided into a greater number of teeth with a flat cutter, and to a rather greater depth, as at E, Fig. 203. Bend backward each tooth to a distance equal to about half a space by any convenient method; for example, by a lever resting at the bottom of each space and pressing against the corner of the tooth, etc. Before bending the first tooth introduce a piece of brass into the space behind it, of a thickness equal to about half this space, so as to avoid bending too far; for succeeding teeth the thickness must be about equal to a space; thus E will become E′. An inspection of Fig. 203 will suffice to make the operation evident; it amounts to bending back a series of separate cutters. The disc is then hardened, and the faces of the teeth are smoothed when they do not cut well; or merely smooth those that are the first to become dull.

It is important to employ soft steel that has previously been well annealed.

=423.= =Cutter for Making Square Spaces.= The teeth of such a cutter can be easily formed with a file, as shown at L, Fig. 209, the edge of the cutter, _f_, being passed backwards and forwards in the direction of the arrows, applying considerable pressure and at the same time slowly rolling _f_ around. Or the cutter may be set up on a short arbor between the centers of the lathe; then pass the file backwards and forwards across the edge until the cuts are formed, slowly advancing the file in the meanwhile, so as to form the cuts around the circumference without once raising the file. The cutter must then, of course, be hardened.

[Illustration: _Fig. 209._]

=424.= =Forming Cutters with a Milling Tool.= The roughing of a round-edged, or even of a square cutter, can also be effected with the aid of a milling or “nurling” tool, proceeding in the same manner as when milling the heads of screws, etc. The tool must be in good condition, well provided with oil, and applied with considerable pressure against very soft steel.

If necessary, the workman can make the mill for himself; it is shown at M, Fig. 210. F shows the method of applying it to the cutter, and by partly turning the mill (of course carried in a strong holder) around its point of contact with the cutter, as indicated by the dotted lines, the rim of F will be evenly roughed all around.

[Illustration: _Fig. 210._]

With good steel fairly satisfactory results are obtained in this manner, but it is needless to observe that such cutters never bite as well as those made in the usual manner.

=425.= =General Observations.= When cutters are used with steel they must be driven at a less velocity than when cutting brass, and, as M. A. Phillippe has observed, it is best to make the cutters for steel of small diameter (about half an inch). They are more easily made and are less distorted in the hardening. The velocity should diminish as the diameter increases; for too great a velocity, especially when the diameter is great, will dull the cutter and soften it, owing to the heat produced.

Cutters must be turned very true: it is advisable to give them a last stroke with the graver after they are fitted to the cutter-arbor that will subsequently carry them.

When operating on steel it is best that the cutter frame of the wheel-cutting engine be advanced by a screw so as to give it a slow and easy motion; the results obtained are more satisfactory than when it is advanced by hand or with a lever.

The following practice is not uncommon in factories when it is desired to reproduce the exact form of a cutter. A notch is made with the cutter in the edge of a piece of steel, X, Fig. 211, or a series of notches _o o′_, etc., can be made by several cutters in the circumference of a disc Z (same figure). After being hardened and sharpened at the cutting edge, this disc is fixed at the center of the division-plate of a wheel-cutting engine, and can then be used to complete the grooving of any cutter that is set in position on the cutter-arbor before hardening. The positions opposite to which the notches were cut should be marked on the chuck, so that they may always be set-square to the cutter.

[Illustration: _Fig. 211._]

=426.= Besides the forms of cutter above described for operating on steel, we may mention that circular cutters may be used in which all the notches around the circumference have been polished, thus removing the burr, and preventing them from acting in the manner of a file. But while, with the former kind, a somewhat rapid rotation is necessary (although not so rapid as when cutting brass), with this latter class the movement must be comparatively slow, and produced by means of a hand-wheel; otherwise they will not cut, since the action depends rather on the application of pressure, and resembles that of a slide-rest cutter. The distance apart and width of the teeth of the cutter, as well as their inclination, are of importance; if too far apart they occasion a waste of time; if too large the machine will act in a jerky manner, and when too narrow, an excessive pressure will be needed in order to make the cutter bite the steel, which, it is to be observed, must always be thoroughly annealed. The edge must be well supplied with oil or soapy water when in action.

It is generally found best to advance the cutter against the edge of the steel rather than across it.

TOOL FOR MAKING CUTTERS.

[Illustration: _Fig. 212._]

=427.= The instruments usually employed for making cutters for the teeth of wheels and pinions are complicated and expensive, but the author has designed one for his own use that is comparatively simple, and can be made by any watchmaker. When the reader has grasped the principle on which it acts he will be able, without difficulty, to modify it so as to suit his requirements.

[Illustration: _Fig. 213._]

The frame B B _b_, Figs. 212 and 213, consists of the body of the tool, B B, and a bar _b b_, which is attached to it by screws. Between the two the division-plate P rotates on an axis E R. The end E of this axis is formed as a chuck to receive the cutter _f_, which is clamped by a screw _t_.

The support S _s_ J is held with friction in the lower part of this frame, to carry the cutter-holder A L M. This cutter-holder is hinged at _n_, so that it can receive a double motion, revolving about a horizontal axis J, and about an inclined axis _n_.

The portion A L of the cutter-holder carries a perforated arbor _a c_, with a ferrule _c_ that receives the tail of the small rose-cutter, which will presently be described.

The end M rests against a guide G, held by a vane _o z_, which is pivoted on a pillar _z_, and can be clamped in either of the directions _z y_, _z x_, or by one of the screws _o_, _o_.

=428.= We will now consider the mode of action of the machine. Having set the little arbor _c a_ in rotation, rest the end M of the arm against the guide, and gradually advance the rose-cutter towards _f_; the edge of _d_ will form the first notch in the grooved rim of the cutter, and then will be raised from contact with it, owing to the influence of the guide G. After moving the tool-holder back to its initial position, advance the wheel P by a tooth, repeat the operation, and so on.

=429.= If the cutter _f_ has to be notched on both sides, it must be reversed on the chuck; turn the guide so as to point in the direction _z x_, corresponding exactly to _z y_; then having set the cutter-holder in the line _z h_, recommence operations. The two grooves of the cutter will then necessarily be of similar form.

Teeth can be cut on the rim of _f_ by using a cutter of the form F, Fig. 214, and holding M against a straight vertical guide.

With a given divided wheel, P, the teeth can be brought nearer together by reducing the diameter of the cutter, and _vice versa_. It is well to have some change wheels, but a better plan is to advance the division plate by the aid of a tangent screw.

[Illustration: _Fig. 214._]

=430.= =To Make the Several Accessories.= _Form of the rose or star-cutter._ The rose-cutter is formed of a mushroom-headed piece of steel. Such a conical cutter is shown at C and R, Fig. 215, and at F, Fig. 214. F and C are cut in the same way that conical cutters are always made, and R is a small triangular prism that only cuts by its three corners, _a_, _a_, _a_. As it is necessarily very small when employed in making the cutters for watch pinions, it must, in such a case, be supported at the neck by a little fork. Moreover, it must be brought gradually against the steel to be operated upon, so as only to engage a very little at a time. With a view to this, it is advisable that the cutter-holder be advanced by a screw.

[Illustration: _Fig. 215._]

The star-cutter, shown at E, Fig. 216, is at times substituted for the rose-cutter. It cuts with the corners _e_, _e_, etc., whether it be going to the right or left indifferently. Or a triangular cutter like T, Fig. 216, can be used in its place; but its angles are fewer and less acute, so that they become dull more rapidly.

A few trials will be needed in order to determine the most convenient rate of movement of the several parts; and the edge of the cutter _f_ must always be liberally supplied with oil. A little can may be so arranged as to allow oil to fall drop by drop on to the cutter _d_, Fig. 213.

[Illustration: _Fig. 216._]

=431.= _To make the guide._ Having mounted a plate, G, on the vane _o z_, trace out the approximate form of the cutter with the point of M; then cut off the superfluous metal, leaving a slight margin. This excess is necessary because the curvature of the guide is not the same as that of the cutter, for the indentations as they spread out from the center (_t_) become gradually deeper. The guide should be tested from time to time by operating on a blank brass disc fixed in place of the cutter _f_ and the guide must be

modified as experience shows to be requisite. Its edge must be saddle-shaped so that the middle may correspond exactly with the two dotted lines _z x_, _z y_, Fig. 213.

The position of the disc on the chuck _t_ must be brought to correspond with the guide by carefully turned washers placed behind it.

=432.= _Driving attachment._ Fig. 217 shows one system that may be adopted for connecting the ferrule C with a driving wheel. All that is required is that the instrument be set in such a position that this ferrule is placed as indicated in the figure with reference to the distributor.

[Illustration: _Fig. 217._]

=433.= _Cutters of uneven thickness at the circumference._ It is well-known that the edges of the cutters of rounding-up tools (=435=) are made to taper off around the periphery. In order to indent such a cutter, the guide must be mounted on a slide, so that it may be gradually displaced while the operation is in progress, by an amount previously determined upon.

The desired result can be obtained with sufficient accuracy by moving the guide backwards by successive stages with a screw. The end _k_ of the arm M, Fig. 213, is slightly tapered, so that a gradual depression of M occurs, and each cut is deeper than that which preceded it.

[Illustration: _Fig. 218._]

=434.= _Modification in the construction._ This instrument may be modified as follows: The disc to be operated upon is fitted to the chuck of the division-plate D, Fig. 218, which is vertical, and the entire system is capable of a movement of rotation round the axis of the base P. Having set the disc in the plane _a b_, as shown in the figure, clamp P; then, by traversing the cutter-holder, the teeth on the side of the cutter towards _a b_ are made. This cutter frame having now been removed, the base P is turned until the cutter is in the plane _c n_, such that it is equally inclined on the opposite side of the axis of the cutter frame; the teeth on that side may then be made, the star-cutter being rotated in an opposite direction.

It is unnecessary to prolong our explanations of the instrument, as the details already given will suffice for any intelligent workman.

TOOLS FOR CORRECTING THE FORM OF TEETH.

=435.= =Rounding-up Tools.= In Europe it is the practice, in making watch wheels, to first notch the circumference by means of a flat circular cutter in a wheel cutting engine, thus forming a number of square teeth. They are subsequently rounded off to the usual form, after the wheels are riveted to their pinions, in a special tool.

The apparatus employed for this purpose is termed a rounding up tool, and its principal feature is a mill cutter F, Fig. 219, the portion _a b_ of whose circumference is cut away and replaced by a guide _g f_ made of steel spring, and so fixed as to coincide with the edge of the cutter at _f_, and incline at _g_ in order to compel the cutter to pass, at each rotation, into consecutive spaces of the wheel. Two screws are provided, the one _f_ for setting the guide opposite the edge of the cutter, and _g_ for placing the free end of the guide opposite to a space.

This tool acts with great rapidity, a fact which has led to its being very extensively used in the factories of France and Switzerland, although the ordinary system of wheel cutting is preferred in England for all the better class of work. For it should be noted that the rounding up tool does not correct any errors that are due to bad dividing; for example, if a wheel is found to have some of its teeth larger than others, the tool can not be relied upon to correct them; on the other hand, if a wheel is exactly divided it is improbable that the employment of this tool will occasion irregularity.

[Illustration: _Fig. 219._]

The instrument we are discussing is, however, not much used by watch repairers, although they are frequently called upon to touch up the teeth of wheels, or to slightly reduce the diameters of their pitch circles, operations which cannot be done by hand with much chance of success. The limited use to which rounding-up tools have been put is owing, in great part, to their high price, but cheaper tools on this principle are now coming into use.

=436.= One of these is shown in Fig. 220. The wheel to be operated upon is held against a small table at D between two vertical runners with guard-pivot centers, and a cutter of the form shown at Fig. 219, is fixed at C to a suitable chuck of a small lathe-head B; this is caused to revolve by the hand-wheel A, a supplementary pulley K taking all strain off the axis. The three milled-headed nuts seen at E, F, and G are for adjusting the instrument; E for moving the lathe-head, so that the cutter is in the same plane as the axis of the runners, a position which is determined by the pointer I; F for advancing the wheel against this cutter; and G for setting the plane of the wheel to pass through the axis of the lathe-head as indicated by the index H. The instrument is accompanied by a number of cutters to suit the various sizes of teeth ordinarily met with, as well as of tables to support wheels of different dimensions.

[Illustration: _Fig. 220._]

=437.= =Ingold Fraise or Cutter.= =Rounding-up Cones.= Either the cutters devised by M. Ingold, or the rounding-up cones of M. Berlioz, may be used for correcting the form of wheel teeth.

The Ingold fraise is a small steel cylinder perforated through the axis so as to be mounted on an arbor, and having a number of longitudinal notches on its circumference which makes it resemble a pinion, the points of whose leaves have been ground off. The spaces of the fraise are of the exact form required to be given to the teeth of the wheel, and their surfaces are covered with fine file cuts so as to enable them to remove metal from the wheel operated on.

Having mounted the arbor that carries it between two centers of a depthing tool (made especially strong for the purpose), the wheel is supported by its axis between the second pair of centers (with guard-pivot points). If now the fraise be advanced by the screw until its teeth engage with those of the wheel, and either be caused to rotate, it will drive the other, and the fraise will thus shape the teeth to a pre-determined form, the faces of each notch acting the part of a minute file introduced between the teeth.

It will be observed that such an instrument is preferable to the ordinary rounding-up tool, in that it may be relied upon to bring all the teeth to the same shape, but, on the other hand, the latter tool has an advantage in being available for slightly reducing the diameter of a wheel when a depth is found to be too strong.

=438.= An objection has been urged against the Ingold fraises on the ground of expense, as each dimension of tooth evidently requires a cylinder specially adapted to it. This fact has led to the introduction of “rounding-up cones” the invention of M. Berlioz, which act on precisely the same principle, but are conical instead of cylindrical, so that each fraise evidently takes the place of a number of Ingold fraises. The total number being proportionately reduced. But great dexterity is required in their use, so that they cannot be successfully employed until after numerous trials.

=439.= =Exact Rounding-up Tool.= The author has devised an instrument for giving to the teeth of wheels the exact form determined upon by theory, but as it is of too elaborate a nature to come into general use, we shall not do more than here refer to it. It is rather of a nature to be used for scientific work, but might be found of considerable value for accurately forming the blades of cutters that are used in grooving the circular cutters employed for cutting the teeth of wheels.

=440.= =To Round Up Teeth By Hand.= We have seen a country watchmaker proceed somewhat as follows: His method was only effective, however, for ensuring the verticality of the file, and did not maintain it straight, nor could the curvature of all the teeth be relied upon to be the same; these two conditions are satisfied by the system here explained.

Formerly watchmakers possessed very considerable skill in this kind of work, as the teeth were always formed by hand; but at the present day, for want of practice, there is not one to be found in a hundred competent to round up a wheel properly by hand alone. Recourse may be had to the following expedient in an emergency; it necessitates the construction of a small special tool, but this is so simple that it can be made in a few hours by an apprentice.

=441.= Take a bar of metal or hard wood, made smooth on its faces and square at the corners (R, Fig. 221), and adapt to it a slide, _c c_, through the center of which a slot is cut to receive a clamping screw; it slides between the four pins indicated in the figure. An arbor _a_ is supported by _c c_, parallel to R, having a plate at its end on which a wheel to be operated on can be fixed by three screws and a loose plate. It is centered by the circumference before clamping these screws, rotating _a_ with a bow, and it may be well to place a piece of tissue paper under and over the wheel in order to avoid scratches. V is a tongue that can be introduced into the space between two teeth in order to prevent the wheel from moving.

[Illustration: _Fig. 221._]

Two arms, _p p_, screwed to the bar R R, support the handle of the rounding-up file _l_, which consists of a large cylinder _t_, _t_, that slides in the arms _p_, _p_. The cylinder T must be exactly parallel to the arbor _a_, and the longer it is the better. The file-holder _s_, also shown detached at Y, Fig. 222, is merely driven onto the rod _t_. The distance between the center of the axis _t_ and the face of the file (_b b′_, Fig. 222) is equal to the radius of the circle that embraces the external curves of two or more teeth, as will be explained.

[Illustration: _Fig. 222._]

The several parts being arranged as shown in Fig. 221, and the bar clamped in a vise at E, it will be obvious that, if the wheel is held in two fingers of the left-hand so as to prevent it from being displaced, while the rod T is moved up and down, at the same time rotating it with the right-hand, the curves of two teeth will be adjusted to correspond with the arc _o o o_ (Z, Fig. 223), and, by transferring the tongue V to the next succeeding space, the curve _i i i_ can be struck.

[Illustration: _Fig. 223._]

=442.= _Observations._ The curvature of the point of a tooth coincides very closely with a circular arc described from a certain definite center, and comprising either two or three teeth. In order to realize these conditions in practice, the slide _c c_ is so adjusted that the axis of T passes just within the circle that passes through _o_, _o_, _o_, etc. (Z, Fig. 223), at which the points of the teeth commence; by making trials with two or three file-holders that differ in regard to the distance _b b′_ (Y, Fig. 223), it will be easy to select the most suitable for producing the required curve. After operating on all the teeth in succession, advance the wheel by means of the screw D, and again work around the circumference, and so on. The progress of the work should be frequently examined with the glass.

It is possible to dispense with the tongue V, and to merely steady the wheel by hand; the work is thus done more rapidly, but must be examined with very great care.

We would insist that the lengths of the two axes are an element of success. In operating on watch wheels T should not be less than six inches long.

By suppressing the tongue the motion of the two axes may be co-ordinated so as to form any theoretical curve; This is the case in the exact rounding-up tool already referred to, but it of course renders the instrument more complicated.

=443.= =To Ease a Train of Wheels.= In very many of the cheaper watches and timepieces now met with in commerce the teeth are rough and badly cut, and the pinions but little polished, so that watchmakers are constantly complaining of the difficulty of securing even a moderately good depth. In such cases they have a simple method to adopt in addition to those already referred to, namely, to polish the teeth with a piece of charcoal.

A piece of smooth, even charcoal, with regular fibre, is moistened with oil or water, and passed across the teeth individually; first with the fibres lying in the direction of motion, and afterwards with them at right angles to that direction.

If the charcoal is carefully selected and lightly applied for a sufficient length of time and no more, the ogives will be found to be nicely smoothed, and the depth will run far more easily than it did previously. It is dangerous to use quick-cutting charcoal, as it is apt to deform the teeth.

Smoothing with a brush charged with charcoal powder cannot be regarded as anything more than cleaning; if the action is too much prolonged the form of the teeth will be spoilt.

TO TEST THE ACCURACY OF CERTAIN TOOLS.

=444.= =Drilling Tool.= First center the runner in the lathe, and ascertain that it is straight, cylindrical, and exactly centered; then fit a ring to it so as to slide with friction to (temporarily) limit the descent of this runner in the vertical stock of the tool.

After placing it in position, adapt to its lower end a collar, provided with a long index of soft brass, which is bent so as almost to touch the plate at its circumference. Rotate the runner and it will be shown to be perpendicular to the plate if the point of the index remains at the same distance from the plate.

As a confirmatory test the runner may be drawn up in the stock, and the trial repeated after bending the index nearly to touch the plate.

=445.= =Uprighting Tool.= If the two stocks or tubes that receive the runners are exactly in line, a runner should move easily through the two at once.

Setting the points in contact in various positions in a vertical line, observe whether they coincide, both when at rest and when rotated together or independently.

First ascertain that the table is at right angles to the axis in the manner already explained for the drilling tool, making the necessary tests with the two runners independently. Then support between their points a short arbor carrying a soft brass index. The position of the lower runner being maintained constant by means of a collar as above explained, rotate the upper one by hand; its friction will carry the index and arbor around, the point of this latter being set close to the plate. Repeat the operation by raising the pair of runners and bending the index down to the same amount.

If in these various positions the point remains at the same distance from the table, it affords evidence that the tool is accurate.

An uprighting tool consists of two parts: the table carrying the lower stock, and the bridge that forms the upper stock. The base of this latter is a ring turned flat and co-axial with the stock, and is fitted accurately into a square groove surrounding the table, where it is fixed by screws.

Any watchmaker understanding this mode of construction will easily perceive when he has tested the tool in the manner above indicated, both what are its faults and how far he can correct them.

=446.= The English uprighting and drilling tools, and some of foreign construction, are combined on the same stand, and a good arrangement, made by Boley, is shown in Fig. 224. It will be seen that the drill can be set in motion by a hand or foot-wheel; the table is fixed in a vise and provided with two dogs for clamping the object. The drilling spindle is perforated throughout its length so that the drill can be held by an American split chuck.

[Illustration: _Fig. 224._]

=447.= =Depthing Tool.= As the value of a depth depends essentially on the overlapping of the teeth being the exact amount required by theory, it is specially important that the tool used for determining the distance between the centers of the wheels and pinions should be of the utmost attainable accuracy.

First ascertain that the spindle which serves as an axis for the two halves of the tool does not change position when they have been several times separated and brought together. For, if this were to happen, and a runner were uneven or the hinge not smoothed within, the parallelism of the two pairs of runners would be impaired.

The runners must be of equal thickness throughout, and should pass with ease from one head to that opposite. Their points and center holes must be seen to be in good condition, and, on placing them in their turns, they must be found to be both true and cylindrical. Having restored them to their places with the points together, move the pair lengthwise from one head to the other, examining the points in successive positions to ascertain that they coincide accurately, both when the runners are loose and when clamped. When the adjustment has been carelessly done the runners will be found to bend under pressure, causing the points to be displaced.

Having set two runners side by side and level, describe with them circular arcs on a smooth piece of brass from centers previously marked, first with the points just projecting from the heads and then projecting more and more. These tests may be made both within and without the tool; so that there will be four sets of tests in all.

It is very important in making the last-named trials, that the tool be maintained at right angles to the plate on which the circular arcs are traced; this condition can easily be satisfied by a special device, or by merely causing the compass to slide along a set-square. It may be added that the series of arcs should be drawn end to end, in order that it may be easier to observe their agreement or difference when examining with the glass.

=448.= When this series of tests has been gone through, and the points have been examined so as to make sure that there is no burr which bends over while tracing the arcs, it is possible to determine the value of the tool; we know whether it is perfect or not,

and what corrections are required. As a rule there are two points mainly at fault; the holes in the heads are not exactly continuations the one of the other, so that they need to be broached out afresh and new runners have to be made. A careful and intelligent workman who is provided with suitable tools will be able, from the information given in this work, to correct, or at least improve, a defective depthing tool; but, as a rule, it will be better done by the maker.

PART V.

REPAIRING AND EXAMINING WATCHES.

METHOD.

=449.= Expedition and certainty in watchmaking and repairing are primarily secured by proceeding on a definite system, both in details of construction or repairing.

The best watchmakers, and practical men generally, take their work in a certain order, from which any departure is exceptional. By this means they avoid the necessity of doing work twice over and of frequently taking up the same piece; a circumstance that often occurs with young watchmakers, owing to forgetfulness or to a want of sequence in their ideas.

They should from the first exercise themselves in working methodically on a definite system.

It must, however, be understood that no method can be inflexible, nor can it be equally advantageous for different individuals, because men differ in regard to manual dexterity, goodness of eyesight and of memory, power of associating their ideas, etc. A system that is suitable to a person of unexcitable temperament will have to be modified by one is oppositely disposed. Everyone will be able to decide for himself as to the best system to adopt and the order in which to take his daily work.

These preliminary observations appear necessary because the method explained below of examining a Geneva watch has been regarded by some as too long and minute. We would urge any young watchmaker that hears such ideas advanced to assure himself that it is a mistake, because the system here explained is only put forward subject to the modifications that experience suggests; and it is to be observed that many of the operations given can be performed more rapidly than they are described.

When a watchmaker experiences a great loss of time, does it not usually arise from the fact that he is obliged to take a watch to pieces, or nearly so, after its repairing and examination were thought to have been completed; or when a watch that has been repaired is brought back to be examined before the ordinary period of cleaning has elapsed?

Let him add together the numerous hours spent in this kind of thankless work, let him sum up the worries experienced, and the discredit, etc., to which he has been subjected, and he will see that systematic work would have saved him both loss of money and loss of credit.

EXTERNAL EXAMINATION OF THE WATCH.

=450.= In the following paragraphs, when the manner in which a given fault manifests itself is not indicated at once, it should be sought in the index of this volume, either under the name of the operation or under that of the object to which it relates. The reader will see for himself which passages refer exclusively to the English or American and which to the Geneva watch.

=451.= =Case, Glass, Dial, Dome.= Glance at the case in order to ascertain that it has not received a blow or been subjected to pressure; that the joints and fly springs work well; and that the hands in rotating touch neither the glass nor dial. By laying the nail on the surface of the glass, it will be easy to see whether there is sufficient freedom between the socket of the hand and the glass. In case of doubt, place a small piece of paper on the hand, close the bezel and tap the glass with the finger while the watch is in an inclined position. If free, the paper will be displaced.

The set-hands square should be rounded at the end and a trifle below the level of any accidental bending of the back of the watch, and the dome must not press on the balance-cock wing or the central dust cap (if present). The above remark also applies to the winding square of a fusee watch.

There must also be sufficient freedom between the going-barrel teeth and the banking-pin of the balance on the one hand, and the internal rim of the case, the fly-springs, and the joints on the other. Otherwise there is danger of contacts when the case is closed which occasion irregularity and stoppage often difficult to detect.

=452.= The dome must be at a sufficient distance from all parts of the movement, more especially the balance-cock. If there is any occasion for doubt on this point put a thin layer of rouge on the parts that are most prominent. Close the case and holding it in one hand to the ear, apply a pressure at all parts of the back with a finger of the other hand, listening attentively in order to ascertain whether the vibrations are interfered with. If the interval is insufficient, a trace of rouge will be found on the inside of the dome. In such a case, if the dome cannot be raised nor hollowed slightly in the lathe (when formed of metal), lower as far as possible the index work and the balance-cock wing and fix in the plate, close to the balance, one or two screws with mushroom heads that will serve to raise the dome.

Ascertain that the hands stand sufficiently far apart; that the hour hand does not rub against the hole in the dial; and that the minute hand does not come nearer to the dial in one place than in another, a fault which may arise either from the dial not being flat or from the center-wheel being badly planted.

Remove the movement from its case, after making sure that it is held steadily by the locking screws; take off the hands, and see that the hour wheel has the right amount of play; this freedom may be diminished if required by laying on the wheel small discs of tinsel cut out with a punch. If the dial presses against any part of the movement, or is not flat or comes so near to any of the pivot-holes as to draw off the oil, it must be ground away until a sufficient amount of freedom is obtained.

TO EXAMINE A GENEVA MOVEMENT.

=453.= Although the following remarks refer in the main to foreign watches with a Lepine movement, very many are also applicable to the English and American watches; further observations specially bearing on them will be found in articles =477-80=.

=454.= =The Motion Work and Hands.= Rotate the wheels connecting the hour and minute-hands by the aid of a key and a glance will suffice to show whether the several depths, which should be light, are satisfactory. The wheels should not rub against one another, the plate, barrel, or stopwork. The barrel should have been previously examined to ascertain that it is not inclined to one side, as if it were, an error would probably be made in estimating the degree of freedom.

The set-hands arbor (the square of which should be a trifle smaller than that of the barrel-arbor) must turn rather stiffly in the center pinion, and the cannon pinion must be held on the arbor sufficiently tight to avoid all chance of its rising and so becoming loose; for this would alter the play of the hands and motion work. If any fault is found in the adjustment correct it at once, so as to avoid doing so after the movement has been cleaned.

If it has not been already done, slightly round the lower end of cannon pinion and the steel shield, care being taken to avoid forming a burr on the pinion leaves. These two pieces ought to rest on the ends of the center pinion pivots, and at the same time be some distance removed from the plate and bar respectively.

=455.= =Freedom and Endshake.= Observe that there is sufficient clearance between the plate and barrel; the barrel and center-wheel; the several wheels in succession both between themselves, their cocks, and sinks; between the balance on the one hand and its cock, the center-wheel, fourth wheel cock, the balance-spring coils and stud on the other. The fourth wheel is frequently found to pass too near to the jewel forming the lower pivot-hole of the escape-wheel.

The end-shake of the wheels may be tested by taking hold of an arm of each with tweezers and lifting it. This may also be done in the case of the escape-wheel, but, when the cock is slight, it will be sufficient to press gently upon it with a pegwood stick, then releasing it, and observing the apparent increase in the length of pivot. At the same time ascertain that the width and height of the passage in the cock is enough to allow the teeth, when carrying oil, to pass with the requisite freedom.

Holding the watch on a level with the eyes, lightly raise the balance with a pegwood point several times, each time allowing it to fall. The variation observed in the space between the collet and cock will indicate the end-shake of the balance-staff.

=456.= =Action of the Escapement.= The side play of the balance pivots in their holes can be easily estimated by touch, or this may be done by the eye, attentively watching the upper pivot through the end-stone with a powerful glass, while the watch lies flat and the lower pivot in the same manner with the watch inverted. If the end-stones are not clear enough, although such a case is rare, remove first one end-stone and examine the pivot; then replace it and remove the other.

It should be possible to rotate the balance until the banking pin comes against its stop, without causing the escape wheel to recoil at all, or allowing a tooth to catch outside the cylinder behind the small lip. The banking-pin sometimes passes too near to the fourth wheel staff. The =U=-arms should rest nearly in the middle of the banking slot of the cylinder: they should be as far from the upper as from the under edge of this slot, so that the end-shakes may have free play in all positions of the watch.

Ascertain that the balance-spring is flat; that it coils and uncoils regularly without constraint; that it does not touch the center wheel, the stud, or the inner curb-pin (with its second coil). The rapid examination of the escapement may now be regarded as completed if the watch in hand is merely being cleaned after having previously gone well.

But if engaged on a watch that has not gone well previously, or if examining a new one, the action of the escapement must be thoroughly tested.

=457.= =Visible Depths.= While the train is in motion through the force of the mainspring or the pressure of a finger against the barrel teeth, examine with a glass all the depths that are visible. That of the escapement, for example, can be easily seen through the jeweled pivot-hole when this is flat, the watch being laid horizontal and a powerful glass used. When the action cannot be seen in this manner with sufficient distinctness, hold the watch up against the light and look through it. Depths that cannot be clearly seen, or about which any doubt exists, must be subsequently verified by touch. (=458.=)

If examining a new watch, it may be found necessary to form inclined notches at the edge of the cocks or near the center hole of the plate so to see the action of the depths. But it is important that the settings of the jewels are not disturbed, and indeed that enough metal is left around these holes to admit of their being re-bushed if necessary.

=458.= =Invisible and Doubtful Depths.= These must be tested by touch, and the requisite corrections applied after having re-polished the pivots, etc., as may be necessary. We would observe that holes a trifle large are less inconvenient than those which afford too little play; providing the depths are in good condition.

=459.= =Length of Balance Pivots: Centering the Balance-Spring.= Remove the end-stone from the chariot and see that the pivot projects enough beyond the pivot-hole when the plate is inverted. Then remove the cock and detach it from the balance. Take off the balance-spring with its collet from this latter and place it on the cock inverted, so as to see whether the collet is central when the outer coil is midway between the curb-pins. Remove the cock end-stone and end-stone cap, place the top balance pivot in its hole and see that it projects a little beyond the pivot-hole.

Place the balance in the figure-of-=8= calliper to test its truth, and, at the same time, to see that it is sufficiently in poise; it must be remembered, however, that the balance is sometimes put out of poise intentionally.

=460.= =Play of Train-Wheel Pivots.= Allow the train to run down: if it does so noisily or by jerks, it may be assumed that some of the depths are bad in consequence either of the teeth being badly formed, or the holes too large, etc. To test the latter point, cause the wheels to revolve alternately in opposite directions by applying a finger to the barrel or center-wheel teeth, at the same time noting the movement of each pivot in turn in its hole; a little practice, comparing several watches together, will soon enable the workman to judge whether the play is correct. The running down of the train will also indicate whether any pivots are bent. Now remove the barrel-bar with its several attachments.

=461.= =Center-Wheel: Bad Uprighting.= Remove the third wheel, and, if necessary, test the uprighting of the center-wheel by passing a round broach or taper arbor through it, and setting the plate in rotation about this axis, holding a card near the edge while doing so. This will indicate at once whether the axis of the wheel is at right angles to the plate.

When a marked deviation is detected, or the holes are found to be too large, they must be re-bushed and uprighted again. When, however, the error is but slight the axes may be set vertical by bending the steady pins a little, in doing which proceed as follows:

Set the bar in its place alone, the screw or screws being a little unscrewed, and rest the side of the bar opposite to that towards which it is to be bent against a piece of brass held in the vise, and strike the farther edge of the plate one or two sharp blows with a small wooden mallet. Experience alone can teach the workman to proportion the blow so as to obtain a given amount of deviation, and must enable him to ascertain whether it is desirable or not to pass a broach through the steady-pin holes before operating as above explained. Some discretion is essential in practising the method.

It is important that the center pivots project beyond the holes in the plate and bar. A circular recess is turned around the outer end of each of these holes so as to form reservoirs for oil. Owing to the neglect of these simple precautions, which are so easy to take, many watches, especially those that are thin, come back for repair with their center pivots in a bad state, because the oil could not be applied in sufficient quantity, and has been drawn away by the cannon pinion or the steel shield.

If the watch has a seconds hand, ascertain by means of the calliper that its wheel is upright. Finally, examine each jewel to see that it is neither cracked nor rough at the edges of the hole.

=462.= =The Barrel: to Take Down and Repair.= The side spring, which must not be too strong, should reach with certainty to the bottom of the spaces between the teeth of the ratchet, and this latter should be held steadily in position by the cap. It is a good plan after making the extensive repairs here spoken of to again test the barrel and center pinion depth, either by touch of by drilling a hole for observation.

The screw of the star-wheel must not project within the cover nor rub against the dial; it must be reduced if either case presents itself. The action of the stopwork must be well assured, especially when the actual stop occurs. It is a good plan to, as it were, “round-up” the star-wheel and finger-piece, with an emery stick, supporting them on arbors. There must be no possibility of friction between the finger and the bottom of its sink.

[Illustration: _Fig. 225._]

=463.= =To Test the Stopwork.= Take up the winding square of an arbor, with the barrel, etc., in position, in a pair of sliding tongs or a Birch key; hold the tongs between the last three fingers and the palm of the left hand, the first finger and thumb being applied to the circumference of the barrel so as to rotate it, first in one direction and then in the other. During this movement, take a pegwood point in the right-hand, and try to turn the star-wheel _against_ the direction in which it would be impelled by the finger; the position is indicated by B in Fig. 225. The tooth that is just going to engage with the finger will thus be caused to take up the worst possible position for being turned, and thus, if the action proves to be satisfactory for each tooth, we may rest content as to the future; providing, of course, that the engagement takes place square, and there is no tendency to cause distortion of the metal. When the corner of C is stopped against the convex tooth of the star-wheel, the finger should be free in a space, and directed towards the center of A. By holding the sliding tongs in a vise both hands can be kept at liberty.

For details in regard to the examination and repair of keyless mechanism, see article =481=.

ACCESSORIES FOR BEGINNERS.

=464.= To facilitate the work by securing order in taking to pieces and cleaning, preventing the screws from being mixed, etc., it is a good practice to prepare beforehand one or more boards, in which grooves and holes are made in positions to correspond with those of the several pieces on the plate of the watch, as indicated by Fig. 226.

[Illustration: _Fig. 226._]

The round holes receive the cock and bar screws, which may be cleaned while the other parts are in the benzine solution. (Two holes are shown side by side for each bar and cock, so that the same plate will serve for a large and small watch). The oval or circular hollows at _a_ and around _m_ receive the cap screws, and _m_ the shield; _c_, _c_, _c_, hold the screws of the side spring and star-wheel and the finger-piece pin; _j_ is for the screws of the top end-stone, and _n_ for those of the bottom end-stone, etc.

It may be well here to mention the very convenient divided boxes for holding the several parts of a watch when taken to pieces that are in general use by watchmakers. They measure about six inches by four, and one inch in depth, thus being large enough to contain all the parts of any ordinary watch.

At first every young watchmaker will find the advantage of noting on paper, bearing the number of the watch, the successive operations that have to be done. He will then merely have to strike them out one by one as the work progresses. As he becomes more practiced he can dispense with this auxiliary.

CLEANING THE WATCH.

=465.= Whatever system of cleaning is adopted it is essential that it be concluded by passing a pegwood point into each of the holes.

Brilliancy is given to the surfaces of cleaned pieces by passing a carefully kept fine brush over them. A brush that is greasy can only be cleaned by soap and water, and a new brush is prepared for use by passing an inclined cutting edge over the ends of its bristles so as to taper them off to fine points, and to remove knots due either to hard parts or to bristles becoming united. This preliminary treatment is completed by charging the brush with French chalk, and rubbing it vigorously on a dry crust of bread until the brush can be passed over a gilded surface without scratching it. The bristles are maintained in good condition by the same treatment. Billiard chalk is also very effective for this purpose, and the greater number of cavities there are in the crust the better it will act. A burnt bone is an excellent substitute for the crust, and has the advantage of causing the brush to impart a very brilliant appearance to objects to which it is applied.

=466.= =To Clean with a Brush.= This method is less used now than formerly, as it can be adopted with safety with the old-fashioned gilding, but is too severe for the thin galvanic coats that are applied at the present day. It may, however, be resorted to for getting up the surface of polished brass wheels, for example.

Put some French chalk or powdered sal-ammoniac (which can be bought at a chemist's) in pure alcohol. Shake the mixture, and with a fine paint brush coat the object with a small quantity of it, subsequently brushing the surface with a brush that is in very good condition. Polished wheels may be made to present a very brilliant appearance by this means, but their teeth and the leaves of pinions must be afterwards carefully cleaned.

The French chalk and sal-ammoniac are all the more effective according as they have remained a longer time in the alcohol; doubtless owing to the fact that the hard grains met with in them are then more completely dissolved.

=467.= =Soaping.= It is advisable to use a soap that quickly produces a good lather; and the object is held in the hand and cleaned by rubbing with a soft brush charged with this lather; then immerse first in clean water, and subsequently in alcohol, moving it about in each: it may be left for a few seconds in this latter, and, on being removed, is dried with a fine linen rag or soft muslin. A stroke with a soft brush in good condition will give brilliancy to the surface. As water sometimes dissolves the soap very slowly, it is desirable that it be employed warm. If about to soap polished wheels, the surface must be first got up with a buffstick and rouge, or by brushing with sal-ammoniac.

The balance spring may be cleaned by laying it on a linen rag doubled, and tapping it gently with a brush charged with lather; then dipping in water and alcohol in succession.

The alcohol may be used hot or cold; its action is, however, more rapid and effective in the former case. But there is no occasion to use hot alcohol except when dealing with substances such as wax, that resist its action.

=468.= =Essences and Benzine.= The employment of essences in cleaning watches is becoming more general every day. They are to be obtained at all material dealers, together with full instructions in regard to their use. A few observations may nevertheless not be out of place here.

The objects are left in the solution for a few minutes in order to allow all adhering matter to dissolve, but they must not remain too long, as certain qualities of benzine, etc., are apt to leave stains. Dry the pieces on removing them, and finish by passing over a fine brush that has been charged with chalk and subsequently been rubbed on a hard crust or burnt bone; as has already been observed, this will produce a brilliant surface on either gilding or polished brass.

The following composition, the ingredients of which can be obtained at any chemist's, has been strongly recommended to us by a clever watchmaker:

90 parts by weight of refined petroleum. 25 " " sulphuric ether.

The objects are immersed for several minutes; indeed, they may remain for a longer period without danger, and on removal from the bath are found to be clean and bright. It must not be forgotten that many of these essences are liable to ignite with the mere proximity of a lamp.

PUTTING THE WATCH TOGETHER.

=469.= The three following rules must be observed in arranging a system of putting the watch together: (1) avoid taking up the same piece two or more times; (2) hold it lightly, as any pressure will produce a mark; (3) keep it as short a time as possible in the fingers. Any linen rags used must be free from fluff, but rags of all kinds should as far as possible be replaced by certain kinds of tissue paper. The best kind will be that which, while securing a given degree of pliability, will best prevent heat and moisture from passing through. Blue-shaded tissue paper should be avoided, as it is often found to encourage the formation of rust on steel work.

=470.= The following order is adopted by some excellent watchmakers in putting together the ordinary form of Geneva watch; it may be adopted exactly or modified as experience dictates.

Commence by putting the several parts of the barrel together, attaching it to the bar and observing the directions given farther on (=474=) in regard to the distribution of oil. Owing to the position of the stop-finger, it is sometimes found that the mainspring must be set up either one-quarter or three-quarters of a turn. Very often one-quarter is not sufficient, and in such cases it is necessary, before putting together, to ascertain that the spring admits of at least 5 or 5¼ turns in the barrel. If it will not allow this amount, and yet has to be set up three-quarters of a turn, too great a strain will come upon the eye of the spring in winding. Fix the chariot with its end-stone on the under side of the plate.

Replace the fourth wheel, making sure that it is free and has no more than the requisite end-shake and is upright. Then the escape-wheel, testing it in a similar manner. See that the teeth have sufficient freedom on both sides of the cock passage, then make the two wheels run together with a pair of tweezers of pegwood, in all positions of the plate, to make sure of everything being free.

=471.= After attaching the index and end-stone to the balance-cock and the balance-spring to the balance (observing that the center of the stud is against the dot on the balance rim), place some oil in both the balance pivot-holes (=476=); adjust the balance to the cock after placing a drop of oil in the cylinder (though a much better plan is that given in article =476=), and set in position on the plate. Some workmen apply a drop of oil to the top of the escape-wheel pivot-hole before setting the balance-cock in its place, but others prefer only to add the oil after the escapement has been tested.

Placing a small piece of paper first between the balance and cock, and then between the balance and plate, ascertain whether the escape-wheel occupies its correct position in reference to the cylinder, in order that the escapement may act properly. This test is especially necessary in dealing with very thin watches or those in which the cylinder banking slot is exceptionally narrow. The barrel bar is now fixed to the plate.

=472.= Set the third wheel in its place, and lastly the center wheel, after putting a little oil on the shoulder of its bottom pivot. Before putting the bar over it, apply oil to the top pivot in a similar manner; then screw it down. After this is done screw on the third wheel cock.

Now apply a small quantity of oil to the two center pivots, and very lightly to the others that have not already been oiled; give a turn to the key and listen to the tick of the watch in all positions. This should always be done before replacing it in the case.

After passing the slightly-oiled set-hands arbor through the center pinion, and adapting the cannon pinion to its end, reverse the watch, passing the end of the center arbor through a hole in the riveting stake, so that the watch is supported on the end of the cannon pinion; a light blow of the hammer on the square end of this arbor will then suffice to drive the cannon pinion home. Some do this before replacing the movement in its case, and some after.

Add a little oil to such pivots as have not already received enough, and fix in their places the remaining parts of the motion work, the dial and hands: the watch then only requires to be timed.

=473.= =Precautions to be Observed in Applying Oil.= The method of distributing and applying the oil is of more importance than might be thought, and has a very marked influence on both the time of going and the rate.

Oil that is very fluid may be used for the escapement and fine pivots, where only a small quantity is needed and the pressure is slight; but it is not suitable in other places on account of its tendency to spread, and thus leave the rubbing surfaces.

If too much oil is applied the effect is the same as if there had been too little; it runs away, and only a minute quantity is left where it is wanted.

=474.= _Barrel._ It is not enough to apply oil to the coils of the spring; some must also be placed on the bottom of the barrel. Before putting on the cover, moisten the shoulder of the arbor-nut that comes in contact with it with oil; by doing so, when oil is applied to the pivot, after the cover is in its place, this oil will be retained at the center of the boss in the cover. Moreover, it will not then be drawn away by the finger-piece, passing from this to the star-wheel.

The oil applied to the upper surface of the ratchet to reduce its friction against the cap must not be in such quantity as to spread on to the winding square. It is a good plan to round off the lower corner of this cover.

=475.= _Center-wheel._ The observation made above in reference to the oil applied to the barrel-cover may be repeated here. By proceeding as explained in article =472=, and adopting the precautions mentioned at the end of article =461=, it is possible to make sure of the pivots lasting for a long period.

=476.= _Escapement pivots: Cylinder._ When the drop of oil is introduced into the oil-cup of the balance pivot-hole, insert a very fine pegwood point, so as to cause the descent of the oil; a small additional quantity may then be applied. When this precaution is not taken, it frequently happens that in inserting the balance pivot its conical shoulder draws away some of the oil, and there is a deficiency both in the hole and on the end-stone.

As has been already noticed (=471=), some workmen place a single drop of oil within the cylinder, and when the escape-wheel advances each tooth takes some up. This method is unsatisfactory, because the earlier teeth receive such a quantity of oil that it runs down the pillars, where it is useless and merely tends to increase the weight of the wheel. A much better plan is to put a very small quantity in the cylinder, and on the flat of each tooth or every second or third tooth. It will thus be evenly distributed, and will not tend to flow away.

The escape-wheel pivots require but a small quantity of oil. It often happens, however, that, owing to carelessness, the workman applies too much, and it runs down to the pinion. The leaves will thus become greasy and stick, while the pivots are running dry.

TO EXAMINE ENGLISH OR AMERICAN MOVEMENTS.

=477.= As has been already observed in article =453=, many of the remarks made in speaking of the Geneva movement are equally applicable to that of English or American construction, and any intelligent watchmaker, on reading articles =450-463=, will be able to select for himself whatever has a bearing on the English watch, without difficulty. It will be well, however, to supplement it by the special directions contained in the four following articles:

=478.= =Case, Glass, Dial, Cap, Dome.= In addition to the points specified in articles =451-452=, the following require attention. See that the position of dial is not altered by closing down the bezel, that the fuzee dust cap does not touch the dome or cap, and that the diamond end-stone or other jeweling of the balance-cock is free of the case. In ¾-plate watches the chain is occasionally found to rub against the edge of the case, or the top-plate to press against the bottom edge of the same, causing the train to bind. See that the balance and chain and the fuzee great wheel are free of the cap, where one exists; the chain is especially liable to rub after the breaking of a strong spring, which may cause the barrel to bulge, when it may also rub against the potence. Ascertain that none of the dial-plate feet or pins touch the train, that the hour wheel is clear of the third and fourth wheel bar, and the minute wheel out of contact with the dial-plate and not pressed by the dial. See that the third wheel is free in its hollow, and that the balance, more especially in oversprung watches, is clear of the barrel.

=479.= =Movement.= The regulator or index must be tested, especially in watches that are undersprung, at several points between “fast” and “slow,” to see that it nowhere approaches too near to the spring, is held with sufficient firmness, and that it never comes near enough to the guard pin for contact to occur. See that the potence screw and steady-pins do not project, and that the barrel does not touch the name-plate, balance-cock, top-plate hollowing or great wheel.

Before taking off the top-plate, notice the position of the detent in the steel wheel, and the amount of its end-shake; the wear of the holes, and freedom of the train wheels; the position of the third pinion with respect to the center wheel, and that of the escape wheel to the lever; see that the banking pins are not loose or bent; that the guard pin, which protects the balance staff when the chain breaks, is near enough to the barrel and the potence. When the watch is taken to pieces, any loose pillars or joints must be secured, pivots examined to see whether worn or bent, and those working on end-stones that they come through the holes. The fourth wheel pinion must be free in the hollow of the pillar plate and the center wheel in its hollow; a similar examination also must

be made of the collet and pin which secure the great wheel to the fusee. If a chain is broken near the barrel end, the stopwork is probably defective or the spring too strong.

The following faults may be met with in the English stopwork. The stop may come opposite the fusee snail too soon or too late, allowing one turn too few or too many of the fusee; or the back of the snail may butt against the stop, and thus stop the watch after going for a few hours. Overwinding sometimes occurs in consequence of the stop-spring being locked between the shoulder of the stop and its brass stud; and the blade of the snail or the end of the stop may be worn or bent in cleaning.

In ¾-plate fusee watches, see that the balance does not come too near to the fusee, fourth wheel, center wheel, and sometimes the escape-wheel. It is to be observed that the breaking of a mainspring sometimes causes certain teeth of the great wheel to be strained.

=480.= =Escapement.= It may be well to note the few following particulars that should always be attended to. See that ruby-pin and pallet stones are firmly set, that neither pallets nor roller is loose on its staff, and that the lever and pallets are rigidly fixed together. The guard pin must be firm, the balance well riveted to its collet, the spring collet sufficiently tight and the curb pins firm. If there is a compensation balance, ascertain that each screws tight. The precautions to be observed in regard to the balance-spring are given in article =456=.

=481.= =Keyless Work.= So great a variety of arrangements of the mechanism for winding watches at the pendant is met with at the present day that it would be impossible to give detailed directions in regard to their examination; the following general remarks, however, mainly taken from the work of M. A. Philippe on Keyless Watches,[6] will be found of value in directing attention to the points which most require it, and will suffice for any intelligent workman. Is should be observed at the outset, however, that the adjustment of keyless work is almost entirely a question of depths, and the workman who has thoroughly mastered this subject will rarely experience any difficulty in dealing with keyless mechanism.

Carefully observe each depth, etc., in succession, to make sure that no prejudicial friction occurs either between teeth or by contiguous parts coming in contact. All springs should act solely in the direction in which pressure is required of them. Special attention should be given to the intermediate steel wheel for communicating motion to the cannon pinion, when this exists, as it is permanently in gear with the train, so that any unevenness of the depth will effect the rate: if the minute wheel have too much end-shake or play on its stud, it is apt to ride on the intermediate steel wheel. The friction of the cannon pinion on the set-hands arbor must not be excessive, since it would involve too great a strain on the teeth of the minute wheel, nor too slight, since the hands would be liable to be displaced on releasing the set-hands stud. If the intermediate wheel has too much end-shake, limit this by an eccentric screw overlapping its edge.

Test the spring of the set-hands stud, to see that it is not too strong nor too weak and that it moves parallel with the plate. Failure in this latter particular might lead to its rising on to the rocking-bar or other pieces on which its acts.

The winding pinion depth must be examined to see that it is neither too deep nor shallow.

The set-hands stud-spring must be strong enough to resist any accidental pressure on the stud, but, on the other hand, the strength must not be excessive, as the spring will then be all the more liable to break, besides causing inconvenience when setting the hands. The course of the spring should be banked at the point which gives a good depth between the winding and intermediate wheels. The minute-wheel stud must be firm in the plate, as any accidental binding might otherwise unscrew it, occasioning the breakage of the dial. When the minute hand is carried by the set-hands arbor, and not by the cannon pinion, care is necessary in fitting this latter, for if too loose it will rotate in setting the hands without carrying the minute hand round, and the minute and hour hand will cease to agree.

It is important that attention be paid to the application of oil to keyless work, as, in its absence, rust rapidly forms, and the mechanism becomes bound. Of course, all bearing surfaces, such as the interior of the pendant, intermediate and minute wheel studs, studs or screws of the rocking bar or other surfaces on which wheels rotate, must be lubricated; an equally important point is to liberally oil the teeth of the winding pinion and the bevel or crown wheel that engages with it. The application of a little oil inside and outside the cannon pinion must not be forgotten.

TO RAPIDLY TIME A WATCH OR CLOCK.

=482.= It seems desirable to supplement the information here given by a few details, since we have observed that, either from want of patience or method, many watchmakers are not always successful in counting the vibrations.

=483.= =To Practice Counting Vibrations.= At the outset it is to be observed that to each vibration to the right there is a corresponding one to the left, so that it is only necessary to observe those in one direction, or else to count one for each two impacts of the escapement, in a minute (or half-minute), in order to ascertain the number of vibrations.

14,400 vibrations per hour correspond to 4 per second; that is 240 per minute, or 120 per half-minute, and the half of this number is 60.

Similarly, a 16,200 train would give 4½ vibrations per second; or 270 in a minute, the half of which number is 135.

An 18,000 train giving 5 vibrations per second, or 150 per half-minute, would count 75 in this interval of time.

This being understood, the required number of vibrations is to be ascertained as follows:

The movement is placed in such a position that the light is reflected from an arm of the balance, so that, by reference to some fixed point, (such as the side of the balance-cock, the stud, etc.), each return of the balance can be noted and counted. A very little practice will remove any difficulty that may be experienced in doing this. When the requisite skill has been acquired, one can listen to the impacts of the escapement while continuing to count, and in order to determine with greater facility the correspondence of the position of the balance with successive pairs of vibrations, close the eyes from time to time while still counting. On opening them, the accuracy of the coincidence can be at once tested by the sight, and, with a little patience, it is possible to count the double vibrations with certainty in this manner, both by the eye and ear; it is only necessary when nearing the end of the minute or half-minute to continue counting aloud, while keeping the eye on the regulator: for the ear will guide the voice, which will thus accurately reflect the motions of the watch.

The above explanations will be sufficient to enable any watchmaker of average intelligence to acquire the power of counting vibrations, either in the manner here recommended, or by modifying it in any manner that may suit his temperament. This power, when once acquired, will be of very great assistance in his daily work, for before taking a watch to pieces that requires repair, he can in one or two minutes ascertain the number of vibrations it should make; he will thus be enabled to regulate the watch almost instantaneously when the necessary repairs have been completed. We would again observe that the main point is to educate the ear to ignore each alternate vibration, and thus to count only the intervals of the balance being in the same position and the same phase of its motion.

=484.= =Vibration Counter.= Leclerre's Vibration Counter is shown in Fig. 227. R is a ratchet wheel with 30 teeth, mounted on a vertical plate, so that it can rotate freely. A pawl, _v_, prevents its movement except when forced forward one tooth at a time by depressing the spring gathering-click, _p_, a finger being applied to the button, _o_, each time the word "ten" is uttered. The number of teeth advanced thus affords a record of the vibrations without there being any necessity to go into higher figures.

[Illustration: _Fig. 227._]

=485.= =To Regulate a Watch.= Place the movement near to a regulator or watch indicating seconds, in such a position that the eye can easily observe the periodical return of an arm of the balance, as already explained, and commence to count, always starting from the instant at which the seconds hand points to zero. Then count steadily 1, 2, 3, 4, etc., until this hand reaches 30 seconds.

Assume, as is very commonly the case, that the balance should make 18,000 vibrations in an hour, or 150 in a half-minute, and that, on counting its vibrations, we find 65 double vibrations, or 130 beats, whereas it should give 150. It is thus 20 beats slow. Advance the index, and repeat the operation; and so on till the regulation is effected.

A greater degree of accuracy will be secured by counting for a longer period, say one, two, or three minutes; but when this is done, it is advisable, in order to avoid confusion, to recommence at one after each 30 or 50 have been counted, because all that is required is the final deviation.

Remarks. 1. All men are not equally quick of perception, so that, in counting and uttering the word _one_, it will be found to correspond with the end of the first beat in the case of some observers, and its commencement with others. By practicing on a well regulated watch, a watchmaker can determine to which of these classes he belongs. If to the second, he should double the _one_

at starting; in other words, he should count thus:

1, 1, 2, 3, 4, 5, etc.

2. Advantage may be taken of the principle of the sounding-board by placing the watch on a sonorous body which will make the vibrations louder, or by placing between the plate of the watch and the ear a rod that is a good conductor of sound. By either or both of these means, the operation is rendered very easy, especially if the vibration counter recording the tens is employed.

=486.= =Another Method of Regulating a Watch.= When the movement is in going order, arrest the balance and make a mark with rouge on one arm of the escape-wheel. Release the balance when the seconds hand of the regulator crosses 60. Observing the number of revolutions that should be made by the escape-wheel in a given time (it would be six turns per minute with an ordinary 18,000 train), count its revolutions while the fourth wheel makes one complete turn; indeed, even this counting may be avoided by making a rouge mark on its edge where it corresponds with the mark already made on the escape-wheel. If after two or three minutes these two marks are found to occupy similar positions at the instant the seconds hand of the regulator crosses 60, the watch is to time. If there is any difference it is easy to ascertain whether this indicates a gain or a loss, and the index is moved accordingly.

=487.= =To Regulate a Clock.= The timing of timepieces by counting vibrations is much more easy than that of watches.

Before removing the pendulum count the number of its vibrations during two or three minutes. This time will be sufficient to afford a guide in regulating the clock after it has been repaired.

In most modern timepieces the escape wheel makes 120 revolutions in an hour, or two in a minute. Hence we have two modes of timing.

(1). Having made a light mark on the circumference of this wheel opposite to a fixed point, observe if the coincidence is maintained after intervals of two or three.

(2). Multiply the number of the escape-wheel teeth by 2, and the product by 120. This gives the number of oscillations the pendulum should make in an hour. Thence deduce the number it should make in two minutes, or the number per minutes can be obtained by multiplying the first product by 2, and it only remains to count the number actually performed in any definite interval.

=488.= =Guilmet's Synchrometer.= When a clock is to time, its pendulum makes a certain definite number of oscillations per minute, dependent on the train. If, therefore, before taking it to pieces a comparison pendulum be set to make the same number of oscillations as that of the clock, or if the former be set to make the number which the train shows that the clock pendulum should perform, it can be used as a term of comparison for setting the clock to time after it has been cleaned. This is the principle on which the synchrometer is based. A pendulum is lightly supported on a frame, and has an adjustable rod sliding in a tube, and graduated so that it can be firmly set without difficulty to give the various periods of oscillation commonly met with in timepieces. The pendulum is hung freely without any train to drive it, and continues to oscillate for two or three minutes, quite long enough to ascertain whether agreement is maintained between the two pendulums.

=489.= =Other Methods of Regulating a Clock.= Various plans have been recently proposed for rapidly timing a clock, all based upon one idea: namely, the temporary addition of a seconds hand for purposes of observation. That suggested by M. Jacomin is recommended by its simplicity.

Having removed the pin and washer that maintain the minute hand in position in an ordinary timepiece, replace them by a light brass cap that can be fixed by a screw or in any convenient manner, so that a fine steel pin projecting from it shall be accurately in the axis of the minute wheel. Part of a watch movement, comprising only the center, third and fourth wheels with seconds hand attached, is supported in front of the clock dial, so that this pin can be inserted in place of the set-hands arbor, and it is evident that, if the clock is to time, the seconds hand should perform one revolution per minute as it will form part of the clock train. The length of pendulum must then be varied until this condition is found to be satisfied.

TIMING IN POSITIONS.

HORIZONTAL AND VERTICAL.

=490.= To adjust a watch so that it has the same rate when first placed in a horizontal and then in a vertical position is a delicate and often difficult operation; thus it is seldom found to be properly done in ordinary watches.

The rates in a vertical and horizontal position are made identical or nearly so by equalizing the resistances that interfere with the motion of the balance in the two cases, and by taking advantage of the displacement of the center of gravity of the balance spring.

Satisfactory results will be obtained in most cases by employing the following methods, either separately, or two or more together, according to the results of experiments or the rates, the experience and the judgment of the workman:

1. Flatten slightly the ends of the balance pivots so as to increase their radii of friction; when the watch is lying flat the friction will thus become greater.

2. Let the thickness of the jewel-holes be no more than is absolutely necessary. It is sometimes thought sufficient to chamfer the jewel hole so as to reduce the surface on which friction occurs; but this does not quite meet the case, since an appreciable column of oil is maintained against the pivot.

3. Reduce the diameters of the pivots, of course changing the jewel-holes. The resistance due to friction, when the watch is vertical, increases rapidly with any increase in the diameters of pivots.

4. Let the balance spring be accurately centered, or it must usually be so placed that the lateral pull tends to lift the balance when the watch is hanging vertical. In this and the next succeeding case it would sometimes be advantageous to be able to change the point at which it is fixed; but this is seldom possible.

5. Replace the balance spring by one that is longer or shorter but of the same strength; this is with a view to increase or diminish the lateral pressure in accordance with the explanation given in the last paragraph.

6. Set the escapement so that the strongest impulse corresponds with the greatest resistance of the balance.

7. Replace the balance. A balance that is much too heavy renders the timing for position impossible.

8. Lastly, when these methods are inapplicable or insufficient, there only remains the very common practice of setting the balance “out of poise.”

If there is a gain in the vertical hanging position of the watch, slightly reduce the _lower_ side of the balance; the oscillation will increase somewhat in extent, and there will be a losing rate in this position.

The converse must be done in the opposite case.

When the vibration exceeds a whole turn, the changes will be the reverse of those above indicated. This fact must not be forgotten, especially in regard to the duplex and lever escapements, which may at first make a vibration of more than a turn, and subsequently less, according to the state of the oil.

We would again observe that the timing of a watch for position presents some difficulty, and it will only be after making a number of trials that the watchmaker will be able to accomplish it with certainty.

NOTE ON THE PROPORTIONS OF BALANCES.

=491.= Two very important elements in the timing are the weight and dimensions of the balance; it is, then, necessary that a watchmaker should practice himself in observing their relative values, and the effect of increasing one at the expense of the other on timing, and more especially on timing for positions.

The _sensibility_ of a balance to variations in the motive force, and the time that elapses between the initial short vibration and the first that is of normal extent, a time that is approximately constant will serve as criteria. A balance that is very sensitive to variations in the motive force is generally too small; and one that attains to the normal arc of vibration almost instantaneously is, as a rule, too light. The converse effects would indicate that the size and weight were excessive.

In order that he may be able to practically apply these remarks, the workman should gain experience by making observations on several watches whose rate is known to be good, in the following manner.

In regard to _weight_: Stop the balance at the position of rest of its spring, then release it and count the number of vibrations up to the point at which the normal arc is attained; the extent of this must have been previously recorded on the plate with rouge marks.

Record the number thus obtained in a table opposite to the dimensions of the balance, and, by comparing these dimensions with those of another balance of equal size, the weight can be ascertained and also recorded.

In regard to _size_: Pass through the center pinion a kind of short screw arbor carrying a large thin ferrule, on which a cord supporting a weight is coiled. Fixing the movement in a movement holder, set it in a vertical plane and observe the extent of the vibrations of the balance with different weights attached to the cord.

These arcs should also be recorded in the table opposite to the dimensions of the balance. With sufficient practice the watchmaker will be enabled to judge at a glance whether the weight and size are well proportioned.

DEMAGNETIZING.

=492.= The following method of removing the magnetism from a watch that has been accidentally brought under the influence of a powerful magnet is proposed by Professor A. L. Mayer. We shall not here enter more fully into the subject than is necessary to indicate the manner in which a watchmaker may restore the steel work to its original condition.

Take a delicately suspended magnetic needle, say a mariner's compass, the length of which is about equal to the diameter of the watch, and lay it on a table. Now place the watch to be operated on, which should not be going, on the table close to the needle and on either the east or west side of it, having previously turned the box around until the needle points to zero. Taking care not to vary the distance between the centers of the watch and compass, observe the number of graduations to which the north end of the needle is deflected with each figure on the dial brought in succession nearest to the compass; it is also necessary to note whether the deflection is towards the east or west.

For example, assume that the watch is on the east side, and that, with noon nearest to the compass, the north end of the needle is turned 12° to the east, that is, towards the watch. This shows that some point in the watch in the neighborhood of the number XII on the dial possesses what is known as "north polarity," and if the deflection had been to the west the polarity would have been "south."

=493.= To take an example. Let the results of a series of trials with the several hours in succession towards the compass be as given in the following table:

========== Hour nearest to the } | I | II | III | IV | V | VI Compass } | | | | | | ----------+----+-----+-----+-----+-----+---- Angle of Deflection | 5° | 18° | 72° | 56° | 22° | 5° ----------+----+-----+-----+-----+-----+---- Direction of Deflection | E | W | W | W | W | E ----------+----+-----+-----+-----+-----+---- Hence Polarity is | N | S | S | S | S | N ==========

========== Hour nearest to the } | VII | VIII | IX | X | XI | XII Compass } | | | | | | ----------+-----+------+-----+-----+-----+---- Angle of Deflection | 17° | 16° | 16° | 20° | 24° | 20° ----------+-----+------+-----+-----+-----+---- Direction of Deflection | E | E | E | E | E | E ----------+-----+------+-----+-----+-----+---- Hence Polarity is | N | N | N | N | N | N ==========

[Illustration: _Fig. 228._]

It will be seen that the greatest deflection westward corresponds to three o'clock, and, in the easterly direction, to eleven o'clock. This shows that the strongest south and north polarity are respectively in these directions. The first thing to be done is, then, to eliminate this particular magnetism. Placing a bar magnet in a horizontal direction, approach the watch to its south-seeking end in such a manner that a line X X′, Fig. 228, through the axis of the magnet, will pass through the center C of the watch, the figure XI, which marks the point of extreme north polarity, being nearest to the bar magnet. Now cause the watch to oscillate so that it alternately takes up the two positions A and B, and, when this has been several times repeated, bring III in a similar manner near the north-seeking pole of the bar magnet, oscillating the watch in the same way. Again try the watch with the compass, repeating the above operations if necessary until the readings are somewhat as follows:

Hour nearest to the	I	II	III	IV	V	VI	Compass						
Angle of Deflection	5°	4°	0°	5°	8°	2°	
Direction of Deflection	E	E		W	W	W	
Hence Polarity is	N	N		S	S	S	

Hour nearest to the	VII	VIII	IX	X	XI	XII	Compass						
Angle of Deflection	4°	4°	2°	1°	0°	2°	
Direction of Deflection	E	E	E	E		E	
Hence Polarity is	N	N	N	N		N	

These figures show that, in counteracting the polarity at III and XI, the magnetic action of the watch in all other positions has, as might indeed have been anticipated, materially diminished. Such a condition of things will, of course, not be attained at once, and it may even happen that the polarity at the two points III and XI is reversed; in such a case it is only necessary to oscillate the III in front of the south-seeking pole instead of the north.

The last table shows that a maximum south polarity is now at V, and north at I. These points must therefore be operated upon in the same manner, and, by proceeding in this manner, and successively eliminating the worst points, the magnetism may be effectually removed.

As proving the efficiency of the above method, Prof. Mayer mentions a case in which a watch lost one hour in six in consequence of magnetism, and yet after the above treatment, it resumed its original rate of about a second per day.

=494.= =Another Method.= A second method of procedure has recently been described by H. S. Maxim. He employs a specially arranged apparatus, based on the principle that if a watch or other object be subjected to rapid alterations of magnetism, while gradually withdrawing it from the influence of the magnetic poles, the distance ultimately becomes so great that the reversals are inappreciable, when the watch is found to be demagnetized. A bar magnet is arranged to revolve in a horizontal plane around a vertical axis; the watch being placed in a small pocket opposite to the magnet, is caused to rotate in an ever-shifting vertical plane, while the frame supporting it rotates in a horizontal plane. While these movements continue the watch carrier is gradually moved away from the magnet by the action of a long horizontal screw, and it is stated that watches that have been completely spoiled can be rendered perfectly free from magnetism by such an apparatus.

PART VI.

PRACTICAL RECIPES.

=495.= The practical operations of the watchmaker are numerous and of a very varied character. Detailed instructions in regard to the proper conduct of a large number of them will be given in this part of the work, and frequent references will be made to former parts of this volume, whenever by so doing repetition can be avoided.

The operations herein discussed are often of so dissimilar a nature that it has been found impossible to classify them in such a manner that will always ensure the reader finding the information he requires without waste of time; and any risk of this would seriously impair the value of such a hand-book as the present. A very full index has therefore been added, and when seeking for details concerning any particular operation, this should in all cases be first consulted.

THE PLATE.

=496.= =To Make a Plate.= The sheet of brass having been prepared in the manner explained in article =103=, roughly rounded and smoothed on one face, is cemented to the chuck of a lathe. Turn out the other face of the plate very flat, and make the circumference square.

When using a lathe the face must first be roughed out, and then the plate is to be cemented to a perforated plate, so that it can be centered and finished. Smooth the exposed face with a well-set cutter and turn the inside and outside of the edge; then make sure that the whole is concentric by a light cut with a cylindrical drill in the center hole. After removing and cleaning the plate it is set up in the dogs, and the face that has hitherto been untouched is gently dressed with the graver.

There will thus be left a narrow ring at the edge that is not touched by the graver: this may be levelled with a smooth-cut file, and the whole surface then smoothed as explained in article =171=.

[Illustration: _Fig. 229._]

If a lathe is not available, the plate must be cemented to an arbor of the form shown at Y, Fig. 229. The heel of this is received in a runner of the turns, while the point of the opposite runner is received by the hole in the center of the plate, which is thereby held in close contact with the plate of Y, the revolution being, of course, produced by a bow. While the cement is still hot, a stick resting on the T-rest will serve to ensure the concentricity of the plate until it is set. This setting may be rendered more rapid by the application of cold water.

Turn out the plate with a hooked graver made of a worn out file, and, if the upper or under side does not run true, turn the portion that projects beyond the chuck with a graver, and, when the plate is removed, face the surface, taking the flat ring produced by the graver as a guide, and taking care to avoid altering any portion of it.

The smaller sinks can also be made in the same primitive manner, to which we have only drawn attention for the sake of watchmakers who are ill-provided with tools. But we would at the same time point out that, at the present day, there should not be a single one who does not know how to extemporize a lathe-head.

=497.= =Cocks and Bars.= If it is required to make all the cocks and bars of a watch, prepare a _false plate_, the thickness of which is a trifle greater than that of the highest cock or bar; then turn on the under side a series of sinks to correspond with the thin portions of the cocks and bars. Cut the several parts out of this plate with a fine saw, and it only remains to shape their contours with a file.

The same method may be adopted if a number of identical cocks have to be made at a time.

THE BARREL.

INCLUDING ARBOR, STOPWORK, MAINSPRING, ETC.

=498.= =To Make a Barrel.= Having trued both faces of the brass, and drilled a central hole rather less than that finally required and exactly perpendicular to the faces, turn away the brass from the inside (leaving a considerable excess of metal at the center to form the shoulder), and form the ring on which the teeth are to be cut, if it is a going-barrel, in the ordinary lathe on a wax chuck. Then fasten the plane surface, which must be quite true, to a smooth plate that is of uniform thickness and has a hole in the center to permit the passage of the pump-center. Having fixed the plate by the mandrel dogs, finish with well-set gravers: 1 the inside; 2 the external cylindrical surface both of the barrel and of the ring left for the teeth; 3 the barrel-cover groove; and 4 with a fine-pointed cutter slightly enlarge the central hole. By this means it is possible to ensure that the barrel will turn true and in the flat. Smooth the inside, more especially the groove, the corner of which must always be carefully smoothed and polished.

The cutting of the recess in the barrel-cover (of a Swiss or French watch) that gives freedom to the motion work, as well as the recesses for the stopwork, will not present any difficulty when the workman is provided with a lathe with or without a slide-rest.

[Illustration: _Fig. 230._]

When there is no slide-rest, the tool shown at D, Fig. 230, can be used for making the groove. A strip of metal of rectangular section has a small cutter clamped in a slot in its surface at a slight inclination. By releasing the two screws of the clamp, this cutter can be advanced to any required extent, and in the strip of metal are two or three slots having different degrees of inclination, so that the one can be selected that corresponds with the depth of the groove.

=499.= =To Make the Star-Wheel Sink.= This is easy on the lathe, the requisite degree of eccentricity being given to the barrel-cover by means of the pump-center.

=500.= =The Cover: Form of the Groove.= As in making the barrel, a thick ring must be left at the middle of the cover to be afterwards removed.

[Illustration: _Fig. 231._]

Fig. 231 is an enlarged figure to show the mode in which a cover is held in its groove. The two are so formed that the cover shall pass into the recess with the least possible resistance, and yet be held firmly without a risk of rotation. It is, nevertheless, a good precaution to fix a pin in the rim so that it shall prevent such an accident.

=501.= =Barrel Hook.= It is necessary to observe that a certain amount of caution must be exercised in regard to the barrel hook, for at least three-quarters of those met with are badly made. A large hook, projecting far into the barrel, as often occurs, occupies a needless amount of space, and at times occasions the breaking of the spring. One that is badly formed or does not project sufficiently allows the spring to escape. A hook should project rather beyond the thickness of the spring; if too thick the spring will be weakened at its eye; if too thin, it is liable to give when the pull of the mainspring is exerted on it.

The circumference of the barrel must be drilled through exactly midway between the bottom and the groove, in a direction that is slightly inclined, so as to resist the pull of the mainspring. A thread is cut in this hole with a conical tap, arresting its advance just before the full threads are reached, in order to make sure that the brass screw to be subsequently inserted shall hold firmly. Then tap the brass wire from which a hook is to be made. Allowing a length to project beyond the screw-plate equal to about one and a half times the thickness of the mainspring, file the two sides flat, round off the point, inclining it slightly backwards, and form the hook with a fine screw-head slitting or other suitable file; then remove the wire from the screw-plate and hold it in a pin vise.

[Illustration: _Fig. 232._]

The angle _a_ (C′, Fig. 232) is now filed down so as not to project within the barrel; any burr that might interfere with its introduction is also removed and the hook is then screwed into its place. It will be easy to ascertain whether the various heights, etc., are correct before screwing it tight home. Then screw the hook into position so that it requires the application of some force in doing so and cut off the external portion level with the surface of the barrel, employing a sharp cutting file. But if it appears necessary to withdraw the hook to make any alteration, this should be done before bringing it to the final position.

Some watchmakers do not take such precautions; they fit a piece of hard brass wire to the hole, beveling off the end that is to form the hook, then cut off the wire nearly flush with the outer surface of the drum and, resting the back of the hook against a piece of steel, give a blow with the hammer so as to bend the point of the hook. But this method, although expeditious, is not the best and it does not always succeed.

=502.= =To Repair a Barrel.= When the play or the end shake of the pivots is considerable, bush the holes with bushings turned on a smooth taper arbor. They must not be riveted roughly, as there is a danger of distorting the bushing or of causing the bottom of the barrel to “cockle.”

If there is any fear that the bushing will be thus distorted or that the barrel will not run true after the operation, it will be well to employ large bushings in which the hole is less than that ultimately required. Then center from the circumference and enlarge the hole, at the same time truing it.

Some practical watchmakers, if the bottom of the barrel is thin, or if special solidity is requisite, fear that the bushing may become loose; they, therefore, enlarge the barrel-hole and make it square; then bush it with a piece of plain brass, and having centered the barrel by its circumference in the lathe, drill a central hole.

It is hardly necessary to observe that, when the holes in both barrel and cover require to be operated upon, a pin should be fixed so as to prevent the latter from rotating in its groove; so that before finally removing the barrel from the lathe, the cover can be put in position to have its center accurately adjusted with a long pointed graver.

=503.= =A Barrel That Does Not Run True.= The remedy for this has just been indicated: enlarge the holes and rivet in them bushings that are either plain or have only very small holes. The two holes can then be accurately centered with a slide-rest and cutter of the requisite form.

[Illustration: _Fig. 233._]

It is a very simple process, and yet there are some workmen who, either from not possessing a lathe or ignorance as to how it should be used, set the barrel on a screw arbor, and, after having topped the teeth, round by hand those teeth which have been touched. This method of procedure is longer than the former and gives results that are worse; moreover, since the screw-arbors are rarely themselves true, especially in regard to the cones, which will be found to have a play on the axis, it is far better to set the barrel in cement on an arbor of the form C, Fig. 233, on the center pin of which the barrel-hole fits without play; the middle of plate C must not be too thickly coated with cement.

=504.= =Barrel Out of Upright.= Several methods may be resorted to for adjusting a barrel that does not turn flat on its axis. Assume that the holes are not too large, for it has just been shown that by bushing the holes and truing them on the lathe, it is always possible to ensure that a barrel shall be true on its axis.

To true it without renewing the holes, first try turning the cover round in its groove by successive short stages, and test its truth each time; the arbor being clamped in a pair of sliding tongs and a card held close to the teeth. If, after the entire circumference has been tested, no point is found that satisfies the requisite conditions, the edge of the cover must be gently hammered (a piece of silver paper being first laid on the anvil so as to avoid marking the gilding) on the side at which the teeth pass farthest from the card and the effect of the operation must be tested. This hammering should be done very carefully and little at a time, and if too great a strain is put on the cover to force it into the groove, some metal must be removed from the side opposite to that at which the hammering occurred. Hence, if the one side is too much extended in the first instance, so that a large amount of metal has to be removed from the opposite side, the operation is liable to be unnecessarily long and difficult. It is hardly necessary to observe that we are here referring to the modern form of going-barrel, in which the cover is on the opposite side to the teeth; in the older form, where the reverse is the case, the opposite edge of the cover must be hammered.

Sometimes a barrel that runs true on its arbor is found to incline when mounted on the plate: such a fault is due either to the barrel holes being too large or to the sink that receives the ratchet not being parallel to the plate. This sink must be trued in the lathe while in position, screwed to the plate of the watch.

[Illustration: _Fig. 234._]

=505.= =To Adjust a Post or Curb in Position.= Make a small punch, a front and side elevation of which are shown at _p p_, Fig. 234; harden it and let it down to a yellow temper at the point. Now fix a flattened ball of lead in the vise, the upper surface of which is so formed that the portion of the barrel that is to receive the hole for the post may rest securely. There is no necessity for the entire barrel to rest on the lead. Place a small piece of mainspring, _q_, within the barrel against the circumference, where it will be maintained by the punch _p_, which will also hold the barrel steady on the lead block. Then give a moderate blow with a heavy hammer on the head of the punch, forcing its point through the barrel.

A burr will be produced outside the barrel, while there will be a corresponding depression within, especially in front of the hole. To secure clean edges, pass a file over the external projection, but only sufficiently to remove its crest, and, resting the inside of the barrel on a lead block, drive inwards the metal that projects; then pass the punch through in a direction opposite to the first and of course with less force. Remove the burrs and repeat the operation first on one side and then on the other with gentle blows of the hammer, removing the punch by hand. Finish with a very fine file, which will entirely remove any external burr round the hole, and one cut with a slide-rest cutter in the inside, followed by charcoal and oil.

A watchmaker that has never performed this operation will do well to experiment with the punch on a small plate of brass, or, still better, on a worn-out barrel.

To insert the post, coil up the mainspring in the winder so as to be able to introduce a slightly conical piece of steel or brass between the two last turns of the spring and near to the hole. Place the post in position and hold it and the spring while the wedge that keeps the coils apart is removed. If the opening thus secured was found to be insufficient, it might be increased by introducing a screwdriver, which is held down until the post is inserted. The making of this curb, shown at _b_, Fig. 234, will offer no difficulty.

[Illustration: _Fig. 235._]

=506.= =Stopwork.= If the pitch circles of the finger-piece and star-wheel of several Geneva stops be measured, it will be seen that three different proportions may exist (Fig. 235), in which the former is less than, equal to, and greater than the latter respectively.

When the finger-piece has a greater diameter, as at _d_, it will oppose an increased resistance to the hand in winding, but the direction of its pressure against the stop will be much below the center of rotation of the star-wheel, because the finger is necessarily very short.

When the finger-piece is very small, as at _a_, there will be less resistance opposed owing to any want of freedom of the star-wheel, and the pressure against the stop will be more nearly tangential, the finger being relatively long; but more care will be required in the construction and, for a given force applied to the key in winding, there will be a proportionately increased pressure against the star-wheel axis.

Inconveniences thus increase in proportion as either piece is enlarged as compared with the other, and the best proportion is secured by making the two diameters equal, as shown at _c b_.

The stud on which the star-wheel rotates should be cut square or, preferably, slightly conical downwards.

=507.= =To True a Star-Wheel.= The form of a star-wheel can be adjusted on the lathe, on the tool shown in Fig. 208, using a cylindrical mill-cutter and adding a stop so that the branches of the tool are always brought to the same distance apart.

Star-wheels can be bought of the material dealers, but they are not always equally divided; indeed, some exist that have been merely punched in the punching press. Hence it follows that many of them are characterized by at least one of the following faults: teeth of unequal length, or with their concavities of unequal form.

[Illustration: _Fig. 236._]

When the teeth are well formed and finished at their ends, but of unequal length, this arises from the star-wheel having been badly centered during the operation of cutting; it must then be re-centered. Take a small brass plate H, Fig. 236, and drill a hole at its center, with a notch at the edge, _a_, to receive the convex tooth without shake. Now place the plate in the lathe and turn out a sink to receive the star-wheel and hold it firmly. The convex tooth will then drop into the notch and the wheel should project a little above the face of the plate. Now release one dog, and, having gripped with it one tooth of the wheel, take a fine-pointed graver and true the central hole and the sink that receives the screw head, taking care only to remove a small quantity of metal at a time.

If the workman has not considerable experience in using the lathe and fears a derangement in releasing and again tightening the dog, he had better remove the plate, cement the star-wheel in position and replace it, when it can be re-centered with the pump-center.

=508.= =To Make a Finger-Piece.= After having drifted the square hole in the center of a steel disc of suitable dimensions, and traced out a line to mark the circumference of the disc and the end of the finger, drill two holes a little beyond this line, leaving such a space between them as to ensure that the base of the finger shall possess sufficient strength; but these holes should be drilled so far in towards the center of the disc that freedom is left for the corners of the star-wheel teeth during its rotation. The head of the finger is at first left so as to exactly fit the spaces of the wheel without play, this being subsequently given with a fine file and in the smoothing.

File the circumference all round so as just not to touch the line traced out; then, putting the disc on an arbor, hold a fine _barrette_ file against the edge, and cause the arbor to oscillate backwards and forwards, the file coming in contact alternately with each side of the finger. This smoothing of the rim will materially facilitate and abridge the final work with the graver. The corner of the rim on one side of the finger having been finished off with the graver edge, reverse the arbor between its centers to treat the other corner in a similar manner. A finger-piece made as here explained will be found to be very true.

Some watchmakers, when it is possible, finish the circumference after it has been adjusted on the barrel-arbor itself; but as a rule this is not necessary.

The slit that receives the pin may be cut as follows: File a square piece of brass to fit the hole in the finger-piece, cut a notch across the end with a screw-head file, and insert it in the square hole. Having centered a flat cutter, the thickness of which is equal to that of the slit to be cut, on a taper arbor, place this in the lathe; resting the brass horizontally on the T-rest (which had better be at the back of the lathe, so that the progress of the operation may be more easily observed) and present the notch to the cutter.

=509.= It will be understood that the foregoing details relate to the method to be adopted in making the finger-piece by hand, but it is very easy to arrange an addition to the ordinary lathe, with or without a throw, for rounding or truing the circumference with great

rapidity.

Having mounted a circular mill-cutter on an arbor in a chuck, as seen at R, Fig. 233, replace the =T=-rest by an upright that has a shoulder, and is truly cylindrical, and of a diameter to fit the support without shake; the finger-piece, D, is fixed to its upper end by a cone and nut, as in the screw-arbor, or by any other means. A lever _l_ is adapted to the vertical rod, so that it can be rotated between two stops on the lathe-bed; such stops are, however, not always needed, because by employing a thick cutter that is smooth on the face there is no danger of damage to the finger. At the same time, if there are no stops, considerable care is requisite in the smoothing and polishing to prevent the sides of the lap touching the finger. This can be polished afterwards in a very short time by using a lap that has been turned on the edge to fit the notch. It is useless to enter into further particulars, as the little appliance or one of an analogous description can be easily made.

The apparatus shown in Fig. 195, and described in article =402=, could be employed for such a purpose.

=510.= =To Make a Clock Barrel.= A strip of soft brass, thicker than the circumference of the drum is intended to be, is coiled into a circle rather less in diameter than the required barrel, on a cylinder of hard wood, either by pressure between the jaws of a vise, or with a mallet or hammer. The two edges, after being carefully cleaned, are soldered with silver solder or brazed, while they are held in position by a piece of binding wire wound round the drum.

Placing this ring on the nose of a beak-iron, harden it by gentle blows, so as not only to harden the brass, but also to increase the diameter and make a true cylinder.

Chuck it on a cylinder of hard wood in order to turn the two ends square, and form the edge that is received in a groove cut in the bottom of the barrel; the bottom is then soft soldered in position. In the older barrels that contained very strong springs, it was often the practice to leave tongues projecting round the drum that entered holes in the bottom and were riveted on the other side.

The barrel may be cemented to a large wax chuck that has as its center a short arbor tapped and provided with a washer and nut, or it may be gripped by its base in the universal head, and the surfaces, etc., finished.

Some of the details given in regard to a watch barrel are applicable here.

The drum is now no longer made by bending a strip of brass, except in country towns, because brass tubing is always to be obtained in cities at metal warehouses, which only needs to be cut into rings of the requisite length.

=511.= =To Make a Barrel-Arbor.= If the metal is in the rough and has the scale on, it must be cleaned either on the stone or with acid. The following method of procedure has been proved in practice to be expeditious:

When the arbor has been turned to shape with the graver, smoothed, and almost polished, it is placed in the barrel and should rotate when in position, but with considerable friction. Then make the two squares as explained below (=513=); and, after smoothing that which receives the finger-piece, set this latter in position on the arbor and see that it does not descend quite to the shoulder. Then replace it by a worn out finger-piece, or by a copper disc that is cut so as to allow of the insertion of the pin in exactly the same position as is required by the finger-piece to be definitively used. It is then easy to drill the pin-hole from either side of the square and to smooth it with a fine broach. Each time that the arbor has to be inserted in the barrel, great care must be taken to remove any burr, as it might damage the barrel holes.

Before hardening the arbor, cut in it two grooves of moderate depth at the points at which the ends must be broken off. Such a practice has two advantages: 1. The two waste points of the arbor can be removed and each end partly formed without employing a file, an arrangement whereby it is possible to maintain in the arbor a maximum of hardness, at least at the winding end. 2. If the arbor is distorted, it will not be in the body, but from the points at which these cuts are made. If any distortion occurs, the blow-pipe jet can be directed on the points, which are then removed with a file before the final polishing.

=512.= To harden the arbor, place it in an iron tube and surround it with powdered charcoal which is pressed down, having previously been well dried. When the whole has been heated to the requisite temperature, throw it into water, and, if the precautions already explained under hardening are adopted, the arbor will be found to be smooth and clean and without either scales or blisters on its surface. Clean and polish it; this latter operation will give the proper freedom to the pivots, although it often happens that a touch with a broach is required in the two holes.

[Illustration: _Fig. 237._]

The bevelled groove within the ratchet teeth is polished by rotating the arbor while a small steel plate, perforated at its center and of the form shown in plan and section at Z, Fig. 237, is held by the hand against the groove. The shoulders can be easily and rapidly polished in the tool represented in Fig. 44.

[Illustration: _Fig. 238._]

=513.= =To Make the Squares. To Make Drifts.= The tool shown in Fig. 238 is used. On the plate P, which is at right angles to the foot S, is fixed a frame that carries two hard steel rollers, _c_ and _d_, the edges of which are extended to form a guide.

A bent finger _b_ is hinged on a screw on the side of the plate, and has a hole _j_ drilled in it, which is continued for a short distance into the plate P.

The following is the method of using the appliance: Fix to the arbor a disc, indicated by dotted lines, in the circumference of which are four equidistant notches to receive the nose of the finger _b_. The rod S takes the place of the =T=-rest and the arbor is placed between the centers of the lathe. As S can be raised or lowered to any position and the runners can be moved laterally, it is easy to bring the point at which the square should commence to correspond with the line _n n_. The finger _b_ having been inserted in one of the notches of the division-plate, reduce the arbor with the file L. Move _b_ to the next notch, and repeat the operation, and so on with the other two sides.

If there is any danger of the finger not maintaining a sufficiently firm hold of the plate, a tight-fitting pin can be inserted in the hole _j_.

At first the arbor should be filed away less than is actually required, and the only adjustment necessary to ensure this is the raising of S to a suitable height. No difficulty need be experienced in this, but, if any doubt is entertained, a screw may be supported from the bed of the lathe, terminating in a rod that passes through the plate P, as indicated at _t_ for example, thus securing perfect regularity in the upward and downward motion of the system.

If a tapered square is required, it will be sufficient to slightly incline the frame by means of two screws _v i_, placed near its left-hand edge with their ends resting on the plate P.

=514.= =To Drill Exactly Through the Center of the Arbor.= Of course, if the old arbor-nut is available, it will afford the best guide for performing this operation, and, if the arbor is tapped, such a hole will not be required. But when neither of these conditions is satisfied, the workman will have two slight difficulties to overcome: the drilling of the arbor and its nut exactly in the center and parallel to the plane of the ratchet. By adopting the following method, he can easily satisfy these conditions:

[Illustration: _Fig. 239._]

=515.= Take a brass disc D, Fig. 239, turned smooth on its two faces. Enlarge its central hole until the barrel-arbor enters it to such a distance that a blow of a mallet will drive it up against the ratchet where it should hold firmly. This disc is chucked on the lathe and a groove is formed that passes exactly through the center. Ascertain by means of a douzieme or a thickness gauge whether the thickness of the disc, measuring from the bottom of the groove to the under side, is equal to the space between the shoulder of the arbor that corresponds to the outside edge of the barrel hole, and the point at which the hole should be drilled. If the thickness is excessive, diminish it from the under side; if, on the other hand, it is not sufficient, fit some thin discs on the arbor, and then force the brass disc to the position thus determined upon. It is hardly necessary to add that when this is done, holes must be drilled to some depth on either side of the arbor, using a drill that does not shake about in the groove although quite free and inclining slightly downwards so that the hole shall not be above the point determined upon, namely, the bottom of the groove. Continue the drilling until the two holes meet, the drill being maintained, during this part of the operation, parallel to the face of the ratchet.

[Illustration: _Fig. 240._]

=516.= If the workman is not provided with a tool for cutting the groove exactly in the axis of the disc, the accuracy that is so essential can be ensured as follows: A brass rod G, Fig. 240, is divided into four at the end as near the center as possible by means of a fine saw or a file that only cuts with its edge, which will be used to form the groove. Set the rod G in the lathe, a center of the form _f_ being inserted at _b_ where the slits cross, and turn down the rod G _b_, although only a little metal should need to be removed, until it enters the hole in the brass disc and projects a short distance on the other side. It then only remains to insert in one of the notches of G _b_ the cutting file or the saw previously used, to form a groove on the surface of the disc that passes

exactly through its center; it is to be remembered that the saw, etc., must only cut with its edge, and should enter the notch with a very slight friction, sufficient to indicate that it fits without play.

=517.= =The Arbor-Nut.= The usual practice is to make the diameter of the nut equal to one-third that of the inside of the barrel. With thick springs of but slight flexibility it must be larger so as to avoid overstraining the innermost coil, and, conversely, with a very thin spring it is diminished, rendering the employment of a longer spring possible. When the nut is too small the spring must be made long, and, by setting up the stopwork, a coil of the spring can be maintained always on the nut.

=518.= _To drill the nut along a diameter._ By means of the rod G, Fig. 240, draw a straight line to indicate a diameter of the nut. This line will serve as a guide for marking two points opposite to one another on the circumference, round which a circle has previously been traced with a graver. The points should be marked so deeply as to ensure that the drill does not displace itself in the initial stages of the drilling; with a little caution, and using a glass, very little difficulty will be experienced in ensuring that the points are in a right line. One of the two following methods may be employed for drilling the nut:

[Illustration: _Fig. 241._]

1. Prepare a brass block of the form shown at _f p f′_, Fig. 241, the space A being cut away, and the end _p_ provided with large-headed screws, shown at _v_, _v_, in the plan. The two faces, _f_, _f′_, must be parallel to each other, and at right angles with the face _p_, a condition which can be easily satisfied by means of the lathe, the face _f′_, for example, being turned towards the headstock, and the dogs introduced into the space A; the opposite face _f_ is then trued with the slide rest. In the vertical face _a a_ make a round hole, through which a pointed center passes, being pressed forward by a spiral or other spring, and the point corresponding exactly with the line _a a_ traced on the face of the brass; of course the axis of this center must be at right angles to the same line. A small block may be inserted within the space A to prevent any flexure of the arms.

An inspection of the figure will make clear the manner in which this little tool is to be used. Having fixed the nut on the face _p_ by the screws _v v_, so that the two points on its circumference coincide with the line _a a_, the whole is placed in the drilling tool with the dogs pressing either on the upper external face or in the space A. After the block is fixed, ascertain by rotating the uprighting spindle that its point coincides in all positions with the top mark on the edge of the nut, and drill as usual. Drill one side, invert the block, and proceed in a similar manner to drill the other.

The little appliance above described might be simplified by being made of the form shown at E, which would require to be reversed when the second hole is about to be drilled.

=519.= =To Polish the Inclined Faces of Ratchet Teeth.= Set the ratchet in slow rotation by means of the foot-wheel, and bring a strip of spring covered with coarse rouge and oil against it from the side, resting the strip on the =T=-rest. In a very short time the teeth will be rounded and polished. This process is similar to that adopted at the present day for polishing the inclines of cylinder escape wheels in the lathe. The position of the polishing spring and its inclination must be determined upon by trial, so as to make sure that the entire surface of the tooth is acted on.

[Illustration: _Fig. 242._]

=520.= Another method is to make a small boxwood lap, and arrange it as shown at M, Fig. 242, so that, when caused to revolve on its axis, which may be more or less inclined, it is brought into contact with the ratchet wheel with its axis, as indicated by the figure. The teeth will cut into the wood, and trace out a helix, as seen at M′, and the lap, passing successively into the ratchet teeth, will cause it to revolve rapidly. When the groove is deep enough, apply some coarse polishing rouge to the surface of the drum; after a few rotations the faces will be found to be polished.

The arbor and lap may be arranged in either of two ways.

Mount the lap between the centers that carry the cutter in a wheel-cutting engine and support the barrel-arbor opposite to it in a vertical direction between the chuck and the bent arm or “gallows” used to fix a wheel while cutting its teeth.

A watchmaker who is not provided with this tool must chuck the lap in the lathe, then mount the barrel-arbor in such a carrier as is shown at _p p_, Fig. 242, and, resting its base on the =T=-rest, hold the ratchet against the lap, determining the most suitable height and inclination by trial; this, he will find, can be easily done.

=521.= =To Polish the Circular Groove in the Ratchet.= It takes a long time to accomplish this by using first, an iron polisher with oilstone dust, then one of copper with rouge and oil. The operation can be performed more expeditiously by using an iron runner, as shown at B, Fig. 243. The end is rounded to correspond with the groove; and the hole, which is indicated by dotted lines, should be large and funnel-shaped, so as to avoid contact with the corners of the winding square when a see-saw motion is given to B in the polishing.

[Illustration: _Fig. 243._]

The arbor being cemented to a chuck in a lathe, hold the end _o_, charged with oilstone dust or rouge, in the groove, and, while the arbor revolves, rotate the spindle B in the hand, at the same time giving it a see-saw motion as above mentioned. A very little practice will be required to do this.

=522.= =Repairing a Barrel-Arbor.= Cement the arbor _a a_, Fig. 244, to the lathe chuck, turn down the ratchet, removing its teeth and thus diminishing its diameter by about a third, as shown at _n n_; then reduce the thickness to a half, turning it down on the side next to the winding square, and continue this square down to the flat disc that remains, taking care that no shoulder is left at the angle between the two. The arbor is now in a condition to receive the new ratchet which has to be fitted.

[Illustration: _Fig. 244._]

Adjust a flat ratchet _r r_ like those used on the barrel-arbor of a fusee watch, which must be of the thickness and diameter of the original ratchet, so that it exactly fits the winding square; turn a sink in it, as shown by the dotted line, to receive the disc already formed; and, if the hole fits the winding square freely but without play, and this square is carried down to the disc, the dust cap _c c_ will maintain the ratchet in its position as effectually as though it formed one with the arbor.

By adopting the above method, which does not occupy much time, it is often possible to avoid making a new arbor when all but the ratchet is sound; and if this portion should again wear out, the necessary repair is still further simplified.

We are assured that arbors repaired in the above manner showed no signs of wear after fifteen years, except that the square in the ratchet was a trifle enlarged, though not sufficiently to interfere in any way with the efficiency; moreover, in modern watches, the winding square is generally long, so that the ratchet can be left somewhat thicker at the center and a corresponding sink cut in the under side of the dust cap to receive it.

=523.= =To True a Barrel-Arbor that is Coned Inwards or too Large.= Cement the arbor firmly to a chuck as shown at C, Fig. 245. With care it will be easy to make the part _e_ run true. As a rule, but very little metal requires to be removed to make _e_ cylindrical or conical in any desired direction, and it will generally be sufficient to finish by polishing with an iron polisher and oilstone dust or coarse rouge and oil. Use a narrow polisher that only bears on the end of _e_, giving it a double movement, straight forward and in a half circle towards one side; or else use a broader polisher, supporting it on the =T=-rest. By inclining this, the iron can be prevented from touching _e_, except near its extremity. It is unnecessary to add that when the arbor has been made cylindrical or coned in a given direction a suitable polisher, bearing on the entire length of _e_, can be used.

[Illustration: _Fig. 245._]

Either of the two following methods can be adopted in the place of that above explained: Support the winding square end of the barrel-arbor in an eccentric runner; let the opposite end run in a small coned hole in the end of a steel runner, which must be polished and hardened so as to prevent the corners of the square that receives the stop-finger from wearing it away; now apply coarse rouge until the fault no longer exists and follow with fine rouge to complete the polishing.

If not provided with an eccentric runner, it will be sufficient to take a tight-fitting key, drive it on with a blow of a hammer and file a point at the tapped end so as to be in the axis of the barrel-arbor. Having attached a ferrule to this key, place the whole between the runners and proceed as explained above.

=524.= =To Renew a Worn Winding Square.= The best plan is to make an entirely new arbor; but when this cannot be done, as, for example, on the ground of expense, the following method of repair may be attempted: Direct the blow-pipe flame on to the square while holding the body of the arbor in a pair of pliers, so as to prevent its being over-heated; and round off the corners of the square, leaving the diameter no greater than is necessary for strength, and tap it with a screw-plate. Now drill a hole at the end of a piece of round steel of somewhat greater diameter than the original square, and form an internal screw by means of a tap made in

the same hole of the screw-plate as was used for the arbor; the end of the tap should be tapered and with good cutting edges.

If the arbor is the full length allowed by the case, reduce the length slightly and screw on the small steel spindle, tapped to the right depth. It must not be screwed quite down to the ratchet, although intended ultimately to come into actual contact. After having thus tested it, form the square, which will naturally be rather larger than the original, and cut a deep groove with the graver at the point where the square is to be broken off, but, before breaking it, harden and let down to a blue or violet temper; then smooth, polish, and screw finally on to the arbor. If this last operation does not result in the square breaking away, grip the spindle in a vise, and, taking the square in a pair of long-nosed pliers, break it with a sharp blow. It only remains to finish off the end in a screw-head tool.

THE MAINSPRING.

=525.= A free and uniform action of the mainspring is one of the primary conditions that have to be satisfied for ensuring a continuously good rate.

=526.= _To make the eye in a Mainspring._ Every watchmaker knows that this is commonly done by means of a mainspring punch; but in its absence a hole can be made by hammering a pointed punch one or more times through the end of the spring after it has been softened, and, after filing away the projecting metal, the hole is broached out or enlarged with the point of a graver and finished with a rat-tail file, taking care that the corners are rounded off so as to avoid the risk of cracks.

=527.= _To reduce the height of a Mainspring._ This and the following method are only to be resorted to when a new spring cannot be obtained.

Introduce the spring into a barrel of less height than itself and wear the steel away by rubbing it on a hard surface charged with oilstone dust, keeping it constantly rotated between the fingers. When the reduction is sufficient remove the spring and draw-file it, so as to round off the two edges; then clean the entire surface.

=528.= _Selecting a Mainspring: Adapting it to a Fusee._ The spring that is characterized by the most uniform uncoiling and the least difference between the force exerted when fully and only partially wound up will generally secure the most constant rate. In selecting one for a going-barrel watch, or in adapting to a fusee, the adjusting rod, shown in Fig. 246, and described in article =530=, is used.

THE FUSEE.

=529.= At the outset, we would state the three characteristic properties of a fusee that have led to its adoption and retention in high-class watches and marine chronometers: 1, it equalizes the motive force; 2, it enables us to use a _tapered_ mainspring, in which the uncoiling takes place in the most advantageous manner possible; and, 3, it secures a longer period of going.

[Illustration: _Fig. 246._]

=530.= =To Adjust a Fusee to Its Mainspring.= Set the barrel and fusee in position in the frame, with the mainspring and chain carefully hooked in their places, and the former set up about half a turn, and grip the fusee square in the clamp, _d n_, of the adjusting rod, shown in Fig. 246; then wind up the mainspring by rotating this lever with the hand until arrested by the stopwork. Now slide the weight _m_, which is held by friction and a light spring, along the rod until a point is reached at which the lever just neutralizes the force of the mainspring, so that the whole rests in equilibrium when left to itself. Rotate the rod backwards by half turns at a time. If equilibrium is maintained to the end, the fusee is well adjusted. But when this is not the case, it will be found that the weight of the lever is too great or too small; showing that the radius of the fusee is either too small or too great. Adjust the lever so that it balances with the radius of the fusee, which is thus shown to be most deficient, and at all other points along the thread of the fusee more metal must be removed to an extent indicated by the experiment.

When not provided with a fusee engine, it is a common practice to use the ordinary lathe, and an equaling file smoothed on its two faces; or a templet might be adapted to the =T=-rest of such lathe.

If the irregularity observed is but slight, it is advisable not to touch the fusee; because, in the great majority of cases, an equipoise can be arrived at by altering the degree to which the spring is set up. Thus, if the weight is too heavy for the lower coils of the spring, set it up more, so as to increase its tension; in the converse case, of course, it must be let down. By trying several springs,

especially if they are of different manufacture, it will very often be found possible to secure a sufficient degree of uniformity without there being any occasion to re-cut the fusee.

CHAIN.

=531.= =To Ease a Chain.= When the links are rusty or not sufficiently supple, the chain should be placed in oil and left there for some hours at least. Round off the edge of a boxwood block, cut a groove across this edge, and clamp the block in a vise; then place the chain like a saddle in the groove, so that it hangs down on either side. Applying oil liberally to the wood, take an end of the chain in each hand, and pull it backwards and forwards in the groove, renewing the supply of oil at intervals. When perfectly flexible, the chain must be cleaned with benzine, or, after soaping, wash it in water and leave for some minutes in alcohol. After being dried, it is dipped in fine oil and dried in a clean linen rag free from fluff, pressing the rag against the edge. A chain treated in this manner will be found to remain supple for a long time, and it will not be liable to rust.

=532.= =Riveting a Hook, Etc.= When riveting either a hook or link to a chain, it is very necessary that the end of the rivet be cut or filed quite square; for, otherwise, the blow of the hammer will bend the rivet, so that the chain will not be square on the barrel, neither will the riveting be firm.

WHEELS.

=533.= =To Rough Out a Wheel.= The sheet brass having been prepared in the manner indicated in article =103=, one face is smoothed with a file, followed by oilstone dust; the plate is then set up in the lathe, to true the other face with the slide rest. On the smoothed face trace out the rim and the crossings. These latter can best be marked out on the dividing plate, or _grammaire_, already explained in article =343=.

[Illustration: _Fig. 247._]

After drilling the small holes, _a_, _c_, etc., Fig. 247, at the corners, cement the wheel to a plate that is perforated to permit the use of the pump center, and remove the metal between the crossings by first turning the sinks indicated by the shaded disc _s_ with the slide rest, and subsequently cut the groove _i i_. Now center the wheel in the lathe, and trace the arcs _a c_ with a fine graver, moving the face-plate backwards and forwards in the manner referred to in article =364=.

Remove the wheel from the plate, and finish off the spaces with a file. Two files will be needed for forming the angles; one a flat barrette file, with the corner beveled off and smoothed to nearly a right angle, to go against the rim of the wheel; and the other a taper file, with faces of the same curvature as the inside of the rim, its two edges being inclined at rather more than a right angle and smoothed carefully. If these simple precautions are not taken, there is a risk of cutting through the arms or making them too narrow.

Many of the details in the following article, although specially relating to a balance, will be found applicable to the construction of other wheels.

=534.= =To Make a Plain Balance.= The round plate of which the balance is to be made must be hammered with the greatest possible care, and of a thickness but little greater than that of the finished balance (=103=). Smooth one face and cement it either to a perforated plate through which the pump center can reach the balance (if the universal head is to be used), or on the chuck of an ordinary lathe, or on the wax chuck C, Fig. 233. Hollow the middle portion with the slide rest cutter or hook tool, according to the kind of lathe used; but, whichever it be, it must be very well set, and only remove a small portion at a time. The application of an excessive pressure will produce a kind of rolling action, which will induce a tendency in the arms to bend. Remove the metal between the rim and boss until its thickness is diminished by about a third; smooth this surface carefully, finishing with a piece of charcoal. The disc is now ready for crossing out.

Place it on the dividing plate (see article =343=) to mark out the three arms, and remove the metal between them, either in the lathe, as explained above, or by drilling a series of holes parallel to the arms and rim. These holes should be so arranged that they can be enlarged with a fine-pointed graver (while the balance rests on a flat wooden block or is cemented to it), and a turn with a sharp edged broach, or the passage of a thin rat-tail file should be sufficient to separate the useless metal. As a rule, the series of holes is drilled with the disc held against a wooden block, but the burrs produced on the under side by the drill prevent it from being maintained flat, unless they are removed after each hole is drilled, and this might occasion a distortion of the disc. It would,

perhaps, be better to cement the rough balance to a sheet of zinc; the color of the shavings would suffice to indicate whether the hole was through.

The arms and rim must be made smooth and even with nicely formed crossing files, the edges of which are smoothed to the most convenient angle, as already indicated.

In filing the crossings the balance should rest against a small block in the vise, and they are rounded while resting in a groove at the edge of a similar block, specially shaped for the purpose. This block is also useful as a support in finishing the angles between crossings and rim.

The under face of the balance is smoothed with oilstone dust; and the arms by drawing the polisher along them while the balance rests on a flat block; it is then cleaned and fitted on a very true arbor, as A, Fig. 233. This should pass through the center hole of the balance without play after a broach has slightly enlarged it, and the balance is clamped by a cap and three screws, _j_. It only remains to set the arbor in the lathe and polish the rim, first turning it to a half oval if desired. In the latter case the rim, after being smoothed, is polished first with coarse rouge on hard pith, and subsequently with fine rouge on softer pith.

=535.= If the arms of a balance are found to be too long, so that they curve, the rim must be lengthened by hammering with the greatest possible care; the inside and outside of it must then be trued on an arbor of the form A.

The boss at the center will be found thicker than is desirable; its height can be reduced with the balance merely adjusted on a smooth taper arbor, but it is necessary to observe that the balance and arbor must not be adjusted to each other by pressing or by rotating the balance with the rim held in the fingers. It must be pushed on or off the arbor by applying pressure at the center of the boss on one side or the other with a piece of hard wood resting firmly against the =T=-rest, while you cause the arbor to rotate.

Instead of the form of arbor shown at A, a screw arbor might be used, with its cone pressing against a cap, but the balance must always be carefully adjusted on the arbor, and this latter must run perfectly true.

=536.= =To Make a Number of Identical Wheels.= If it is desired to make a number of brass wheels of the same size and shape, the workman will find it much to his advantage to employ the punching machine. By adopting the following method he can make his own punches and bed-plates.

[Illustration: _Fig. 248._]

With a view to secure same length in the matrices that are used for forming the crossings, without augmenting the difficulty of construction, proceed thus: Each of the pieces V, V, Fig. 248, consists of two parts: 1. The star-piece, _a c b d_, of three, four, five or six arms, according to the number of crossings of the wheel. 2. The collar, V. The star-piece is of the same length as the collar, and is made in the wheel-cutting engine in the same manner as the leaves of a pinion. The punches, of which one is shown at P, are fitted by hand to the recesses of the star-piece, and then cemented in position; the whole is then chucked in the lathe and turned as one piece, so that its diameter is slightly greater than the interior of the collar. Now harden the star-piece, and temper it to a blue color. When cold harden the collar V _v_, and temper it to the same degree, but, while expanded by the heat in tempering, introduce the cold star-piece and drive it home. By proceeding in this manner, no subsequent hand fitting will be required. V _n_ must not be hardened.

Tools for punching the crossings of wheels are sometimes made on this system in which the disc of brass is fixed to a support that can be made to revolve by quarters of a revolution at a time, and a single punch serves to remove the metal by four separate operations. But as a rule it is better to use four punches together.

=537.= =To Repair Wheels.= When the teeth of a wheel are damaged, the only possible remedy is to provide a new one. If, however, a single tooth is broken, the following method can be adopted, on an emergency, for inserting a new one:

[Illustration: _Fig. 249._]

=538.= _To insert a new tooth in a wheel._ Cut a small notch in the rim of the wheel, shown at _a_, Fig. 249, which should be dovetailed if possible, and the two sides spread out slightly from the upper towards the under side, as indicated at _c c_. Cut a small piece of well-hammered brass, of the form B, so that the part _d d_ fits exactly into the notch in the rim. Now invert the wheel and grip it near to _a_ in a pair of long-nosed pliers, which must be held in the vise. Moisten the inner faces of the notch with

soldering fluid and, placing B in position, put particles of solder round its edge; holding the lamp beneath the nose of the pliers, the solder will presently melt, and a drop of the fluid should be added to facilitate its running into the joint. Cool the wheel and wash thoroughly, first with water and subsequently with alcohol.

It only remains to file both faces smooth and level with the rim of the wheel; then shape the tooth carefully.

By introducing B from the side opposite to that which is visible in the watch, and sloping the faces _d d_, to a less degree than _a_, the inverted wheel will present a recess to receive the solder; so that, on looking at the upper surface, at which the edges fit very closely, the joint will be scarcely visible.

=539.= _To true a wheel._ When the teeth are found to be in good condition, but the wheel does not run true, or one or more of its arms are strained, the fault can be corrected, in a case of absolute necessity, as follows:

Remove the pinion from its wheel. Enlarge the central hole in the lathe and rivet or solder in it a brass ring that is slightly thicker than the wheel, and perforated with a smaller hole than that required for the riveting. Now center the wheel from its circumference; increase the central hole with the slide-rest cutter, and turn down the two faces of the ring level with the wheel. Rivet the pinion in its place, after testing the truth of its riveting neck, when the wheel should be found to turn both true and flat.

If the wheel under repair is likely to be subjected to much force, at least two small notches should be left in the enlarged hole in the wheel to receive corresponding projections in the brass ring.

=540.= If the _crossings of a wheel are broken_ and the wheel cannot be replaced, it must be chucked in the lathe and the arms turned out with a graver, the inner edge of the rim being at the same time turned circular, and a step turned on this edge where the metal is to be left of half its original thickness.

Take another wheel of the same size and thickness, or a plain disc, and turn it of the same diameter as the outer ridge of the step; reduce its thickness at the edge by one-half and a disc will thus be obtained with a ridge round the edge corresponding exactly with that of the wheel, and the one will fit in the other. They are, of course, soldered in this position, care being taken to prevent the solder from reaching the teeth, and the old wheel will thus be provided with a new interior.

If the disc is made to fit closely on the upper side, a wedge-shaped ring being left to receive the solder in the manner explained in article =537=, the joint will be scarcely perceptible on the exposed face, even with a glass.

In repairing delicate wheels in any way it is a good precaution to cement the rim to the edge of a hole in a brass plate, so that only the arms or other part to be operated upon is exposed.

=541.= =To Make a Stem-Wind Wheel.= We will suppose that the old wheel is available as a pattern; if it is not, the several dimensions must be ascertained by calculation in accordance with the laws of depths.

[Illustration: _Fig. 250._]

Prepare a thick plate, and drill a central hole, fitting a steel pin into it as shown at _o d_, Fig. 250. The diameter of _d_ must be exactly the same as that of the pump-center in the universal head. Fit the wheel-blank R to the pin _o_ without play, and cement it to the plate. Remove the pump-center and insert _d_ in its place, clamping the plate P firmly against the face-plate by the dogs. By using well-sharpened gravers or cutters, the wheel may be rapidly shaped.

The pin might be forced in from the under side to the level of that face of the plate; and if it were perforated as shown by the dotted lines, it might be centered by means of the pump. Or the plate P might be made circular and centered from its circumference.

=542.= To cut the teeth on the circumference the wheel need only be fixed on the chuck of the wheel-cutting engine as usual by means of the steel cone. The crown teeth are cut while the wheel is firmly cemented to a pin-chuck like that used in turning it.

Other keyless wheels can be made on the same principle, and such modifications as may be necessary experience will suggest. Sufficient information in regard to wheel-cutting has already been given in =397= and following articles.

PINIONS.

=543.= =To Make a Pinion.= At the present day pinions of all sizes can be obtained of the material dealers, so that it is very seldom that a watchmaker is obliged to make one for himself.

In an emergency, however, he can adopt the following method for making one out of the ordinary drawn steel; but it should be added that, in all probability, some practice will be needed before success is arrived at. Cut a length of steel wire of suitable diameter about two-thirds as long as the files that are to be used for shaping the teeth. Turn it down to form the axis, leaving a block near each end equal in length to the required pinion, as if three pinions were to be made on the same staff. Then cut and round leaves on all, keeping the file always in contact with a leaf of each pinion. By proceeding thus the sides and roundings of the leaves will be maintained parallel to the axis, and there will be no risk of the pinion being barrel-shaped, as is nearly always the case when a short pinion is held in the fingers or rested on a block in the vise.

Proceed in the same manner in smoothing and polishing, using pieces of some close-grained wood, such as walnut.

It is much easier to make the pinion of the required form by means of a revolving cutter in the lathe, if the workman is not provided with a special tool for the purpose: the arrangement of the lathe is described in article =402=.

In some factories the leaves are cut in two operations: a cutter with plain fine saw teeth divides the circumference into the requisite number of equal parts, the leaves being subsequently made of the correct shape by a special cutter, the method of making which has already been very fully explained in articles =417-435=.

=544.= =To Determine the Size of a Pinion.= The following table is usually employed for this purpose. See also =562= and the following articles.

To give the approximate diameter of a pinion, the pinion caliper should include:

For 16 leaves, 6 full teeth; that is to say, measuring the distance between the two external faces; ” 15 ” rather less than 6 teeth, or 5 teeth, and just beyond the point of the sixth; ” 14 ” 6 teeth, measuring at the points. ” 12 ” 5 teeth, measuring at the points (or rather 4½ teeth); for a clock-wheel, 5 full teeth; ” 10 ” 4 full teeth; for a clock-wheel, 4 _squared_ teeth; For 9 leaves rather less than 4 full teeth, or 3 full teeth to the point of the fourth; ” 8 ” 4 teeth, measured at the points, minus a quarter of a space; ” 7 ” rather less than 3 full teeth; for a clock-wheel, 3 full teeth, plus a quarter of a space; ” 6 ” 3 teeth, measured at the points, or rather more; for a clock-wheel, 3 full teeth.

It is important to notice that these measures can only be regarded as a first approximation, and it is only by actual trial in a depth-tool that we can be certain that a pinion is correctly sized. By taking the measures in a micrometer, or other accurately divided gauge provided with a vernier, the work of selecting will be much abridged; but how long will it be before the generality of watchmakers will make use of these convenient appliances? The well-known wheel and pinion sector, although convenient, is not equal to them in point of accuracy, and is affected by an error in measuring a chord, not a true diameter of the wheel or pinion.

=545.= =To Increase or Decrease a Pinion.= The pitch circle of a pinion may be increased by reducing the thickness of the leaves in such a manner that their flat faces are continued further on to the rounding; conversely, a pinion may be decreased by carrying this rounding farther down towards the base of the leaf.

=546.= =To Decrease a Pinion Without Removing the Wheel.= Some watchmakers recommend that the wheel be removed from the pinion, and, after the necessary reduction has been effected and the leaves re-polished, again riveted on the pinion-neck. Very few workmen, however, can do this well, so that after the operation the wheel is seldom found to run true. If a new pinion cannot be procured, the old one must be reduced.

When a pinion that is too large is replaced by one that is smaller, it is necessary to take care that the hole in the wheel is well centered and not too large; in either of these cases it must be enlarged and bushed after being centered by the circumference.

=547.= =To Polish Pinion Leaves Mechanically.= It was formerly the custom to polish the leaves of a pinion, holding it on a block or between two fingers and traversing a strip of metal with oilstone dust backwards and forwards in each space for the smoothing, and a similar strip of walnut wood (with rouge) for polishing.

This method has long been abandoned in factories, where all pinions are polished in a machine.

We will proceed to explain a simple arrangement for polishing pinions in the ordinary lathe, but it is advisable first to describe one form of tool that is actually in use on the large scale for this purpose. The two only differ in their dimensions.

=548.= _Pinion-polishing Machine._ A frame B B, Fig. 251, supports at its upper end an =H=-shaped piece, of the same form as the cutter-holder in an ordinary wheel-cutting engine; but the arbor, instead of carrying a cutter, is provided with a wooden drum R. On the base of the frame is a plate P, which can be fixed by the screw E, and carries a second plate _p_ to serve as a bed for the slide, which supports the pinion to be polished freely between two brackets _a_, _a_. The plate _p_ can be set a little oblique and clamped by the screw _v_.

[Illustration: _Fig. 251._]

The machine acts as follows: Present a corner of a pinion-leaf to the circumference of R (which is caused to revolve by a cord passing round the pulley _n n_), the axis of the pinion being not quite at right angles with that of the drum, in order that the groove formed in the soft wood may resemble the thread of a screw, and so cause the pinion to revolve. When the groove is of sufficient depth, apply rouge if operating on a small pinion, and emery for a large one: after a few turns of R, the slide carrying the pinion being at the same time moved backwards and forwards, the pinion will be found to be polished. A better surface can be obtained by using flour emery.

The steel wheels of keyless work can be polished in the same manner.

=549.= The spindle of the screw E passes through a rectangular slot in B in order that the slide and its support can be moved parallel to the axis of R.

The grain of the wood must be at right angles to the axis of rotation of the drum, and a wood that is non-fibrous is preferable. It must evidently not be too hard, and, if too soft, the thread formed on its circumference will get rough, and often will suddenly change position. When the entire surface has been worn it must be re-turned smooth and cylindrical. The larger a roller is, the quicker it will polish and the less it will wear. Moreover, it will render a proportionately less amount of motion of the slide necessary. The root of the walnut tree is especially sought after, but, when this cannot be obtained, other woods can be used.

In factories where clock pinions are made, thin discs are employed in place of the drums. They are at least a decimetre (4 inches) in diameter, and very narrow at the edge, and can be re-turned with a graver when worn without being removed from the tool, if a =T=-rest be fixed in some convenient position.

The screw _d_ is for limiting the descent of the drum, but some workmen prefer to dispense with it, and, instead, hold the frame C C in the hand, pressing it gently against the pinion. They urge that the wood is never of the same degree of hardness round its circumference, and therefore must of necessity wear irregularly; by holding C C in the hand the pressure on the pinion can be more evenly adjusted, as it is possible to feel at once whether the drum is polishing or scratching.

The inclination of the slide to a plane at right angles to the axis of R is measured by the pitch of the screw formed on the drum. But in practice no special precautions are taken, and it is only necessary to incline the slide slightly to the right or left, until the pinion is found to revolve freely.

The drum may be from two to three inches in diameter, and, in order to ensure the same degree of hardness throughout the entire circumference, it is a good plan to make the drum of a series of wedges cut so that the grain in all radiates from the center. Beautiful polished surfaces are obtained in this manner.

[Illustration: _Fig. 252._]

=550.= _To polish a pinion in the ordinary lathe._ Various methods may be adopted, but the following is one of the commonest:

Support the pinion between the two centers _b_, _d_, of the pinion-carrier shown in Fig. 252, the form of which will be evident without explanation. Rest this carrier by the portion M against the =T=-rest, pressing it against the drum at the same time with one finger. Rotating the drum first by hand, make the pinion cut a groove varying the inclination until it is found to be correct, and, when sufficiently deep, charge with polishing material, and rotate it with wheel, at the same time moving the pinion-carrier backwards and forwards endwise. A little experience will give the requisite skill.

If the pinion is not held at a sufficient inclination it will scrape and will not revolve. If too much inclined, only the roundings of the leaves will be polished, the sides being left untouched. A well-formed groove will last for a long time.

=551.= =To Tighten a Cannon Pinion.= If it is simply slack it will be sufficient to increase the diameter of the set-hands arbor as described in article =336=. But if the cannon pinion is in the habit of working off this arbor when setting the hands, the arbor can be tapered a little downwards; or proceed as follows:

[Illustration: _Fig. 253._]

Drill a hole in the square that receives the minute hand in the position shown at _a_, Fig. 253, and also indicated by dotted lines at _c s_; now turn a groove round the arbor, also shown by dotted lines, at the point _n_, to correspond with the hole _a_. Insert a pin in this hole, filing it off smooth with the surface at the side at which it enters, and nearly level at the other side, to be hammered over just sufficiently to prevent the pin from working its way out. The cannon pinion will now be found to turn with the requisite degree of friction, and without any tendency to work up. It will last all the longer if both the pin and the groove in which it works are polished.

SET-HANDS SQUARE.

=552.= =To Make a Set-Hands Nut.= This is a small square nut pinned to the pivot of a solid cannon pinion that projects beyond the top-plate in some watches after passing through a hollow center pinion. This construction has been latterly discontinued, but it may be well to explain the mode in which such a nut can be renewed when necessary.

[Illustration: _Fig. 254._]

Take a rod of soft steel of a diameter half as large again as that of the square to be made. Drill a hole along its axis rather less in diameter than the set-hands arbor and cut off the ends a little longer than the square is required to be. Put this nut on an arbor and turn it flat on each end (although still a little long) and truly cylindrical. Having inserted a loose fitting coned brass wire of oval section into the nut, hold it on its side on an anvil. With a sharp blow of the hammer cause the cylinder to assume an oval form, so that the round hole is as seen at A, Fig. 254, this being the section of the end of the set-hands arbor itself. If the work has been carefully performed up to this point, the steel nut should now pass a short distance on to the arbor on applying a moderate pressure, and it will suffice to slightly alter the form of this latter in order to ensure a perfect fit. As there should be no shake, it is advisable that this adjustment be made after the nut is hardened.

File the two faces _d_ and _f_ parallel to each other and to the axis of the oval, reducing the total thickness very nearly to the amount ultimately required, then holding the nut in the pincers by these two faces firmly, but without scratching them (or it may be held by a rod fitted to the oval hole), form the square, removing all the metal that is beyond the two vertical lines in the figure. Then set it on an oval arbor and turn the corners down to the exact diameter required; pass the graver over the two ends so as to adjust the length. It will then be easy to finish off the square and round the lower end, holding the nut on a steel rod in a pin-vise. Drill the hole for a pin after marking its two ends on the nut as explained in article =518=, then, holding the nut so that it rests on its lower face, form a recess with a chamfering tool held in its axis; the form of this can be modified if required with the rounded end of a rod and oilstone dust.

Harden the square and temper it to a blue color; then smooth its faces and ends, and fit the square to the set-hands arbor. The hole for the pin must now be made through this arbor, taking care not to allow the square to rise out of its place during the operation. It only remains to polish the recess formed in the nut with a rod rounded at one end and rotated with a ferrule, and finish off the corners with a burnisher and rouge; the lower end is finished in the same manner as the head of a screw.

=553.= We have here considered the case of a new arbor, but, if fitting a nut to one that is already drilled, proceed as follows: Make the nut rather longer than necessary and drill a hole higher than the point at which measurement shows it ought to be; then remove metal from the lower face until the two holes coincide. The work is simplified if the nut be made of the correct height at once and, instead of drilling a hole, a slit be formed as in the head of a screw, the bottom of which must correspond with the lower edge of the hole in the arbor.

=554.= =To fit the Set-hands Arbor to the Center or cannon pinion.= We have pointed out in article =364=, the objections to hammering the set-hands arbor so as to secure sufficient friction to make it hold in either of the pinions through which it passes in the ordinary form of watch. Tracing a spiral line on its surface is not much better, as the metal thus caused to project soon wears

off. A better method is explained in article =337=, but, when only a slight increase of diameter is needed, the following will suffice:

Roll the arbor on a hard flat wood surface with a file of medium cut, applying considerable pressure so that the arbor is forced against the file. If the pressure is sufficient and maintained long enough, a dead rough surface will be formed on it which will increase its diameter so that it will retain a small quantity of oil. It is well to roughen the surface rather more than necessary, subsequently passing a burnisher lightly over it until the arbor fits the pinion with sufficient friction.

As to the making of a set-hands arbor, it will present no difficulty to a watchmaker of even average skill in turning and filing.

PIVOTS.

=555.= =The Play Of Pivots.= It may be accepted as an approximate rule that the play of escapement pivots in their holes should be as follows:

In the cylinder escapement, about one-sixth the diameter of pivot.

In the duplex escapement, about one-tenth the diameter of pivot.

In the lever escapement, about one-eighth the diameter of pivot.

A large hole causes the pitching of the depths to vary with position, and a deficient play renders the escapement more sensitive to thickening of the oil.

The depth of a pivot-hole or the length of its cylindrical acting surface may be taken to vary inversely with its hardness. Thus a ruby hole is made less deep than one of brass.

=556.= =To Replace the Pivot of a Hollow Pinion.= It often happens that the pivot of a hollow center pinion is so deeply cut that it cannot be re-polished, in consequence of the careless manner in which too many examiners finish the center holes (=461=). If the pinion itself is found to be still in good condition, it can be made serviceable as follows:

Cement the pinion, with its wheel attached, firmly to the chuck of a lathe after having removed the two worn pivots, and, when it is accurately centered, increase the hole by means of a drill that is a trifle larger than the original pivots (see article =282=); in the hole thus enlarged and carefully smoothed insert a close fitting steel tube that has been hardened and tempered to a blue color, which must be smoothed and run true. The portion of this tube that projects on either side is then adjusted to the proper length, and it only remains to polish the pivots.

If only one pivot requires renewal, ascertain whether there would be sufficient hold with the hole enlarged through half its length, and proceed as already explained.

We have assumed that the shoulders of the original pivots can be made to serve again, but it often happens that the shoulders do not possess sufficient substance, in consequence of the hollows being cut too deep. In such a case it is hardly necessary to observe that the hole must be drilled larger, so that, after the tube has been adjusted, new shoulders can be turned on it.

=557.= =To Redress a Bent Pivot.= For this purpose some workmen merely use a pair of pliers or tweezers; others place the pivot in a slot of the Jacot tool, and press on it with a burnisher that has little or no cut, at the same time causing the staff to rotate. Either of the two following methods may be adopted:

Drill a number of straight holes in a plate exactly at right angles to its surface. Now introduce the pivot into a hole that it fits with very little play, and redress it by causing the staff to rotate, at the same time holding the plate in the hand. Caution is necessary since there is some risk of bending the pivot too far.

=558.= =Pivoting a Cylinder, etc.= This operation will not present any difficulty if the several heights are properly taken. See also the articles on Beaupuy files (=240=), and on compasses for measuring heights, etc. (=243=).

=559.= =Polishing Pivots in the Lathe.= Pivots are as a rule polished by metal polishers provided with suitable materials, and held in the hand; in Fig. 255, however, is given the design of a machine by which this work can be accomplished when the pivoting is done in the chuck-lathe, the pivot itself being free and unsupported by a runner.

[Illustration: _Fig. 255._]

The bed P of the instrument carries a wheel R which engages with a pinion on the axis of the polishing lap _m_. The wheel R is mounted on a clock stud passing through a slot and fixed by a nut, so that the pitching of the two mobiles may be modified; motion is communicated to the lap by simply placing the finger against the teeth of R. The bed can move in a vertical plane, being pivoted on two screws, _v_, _v_, and the block that receives the points of these is riveted to the disc _d d_, which can be made to rotate, with friction, on the second disc _n n_. This latter is riveted to a plate _e_ fixed at the end of a cylindrical rod F.

It will be evident that if the rod F is inserted in the =T=-rest support, the plate P extending towards the back of the lathe, this plate can be raised or lowered, and moved towards the right and left, so that the flat face of the lap can always be brought in contact with the pivot that is to be polished. This latter is caused to rotate by a foot-wheel while one hand holds the raised plate by the button _a_, and a finger of the other hand is applied to the teeth of R, causing the lap to rotate.

The upward motion of P may be limited by the edge of the top _s_ of the button _s k_, which is tapped so as to rotate with stiff friction on the pillar H. The stop _l_ is to prevent the polisher from traveling too far towards the left and thus removing too much from the shoulder that is to be polished. The screw _x_, giving motion to the slide _y_, is for securing parallelism between the pivot and the surface of the lap, according as the former is cylindrical or conical in shape.

For fine pivots it is advisable to introduce an additional wheel and pinion. The finger will then be better able to appreciate the degree of resistance opposed, and, owing to the increased velocity, it will be useless to use oilstone dust, but rouge can be applied directly after the turning. At _e_ is a steady-pin for maintaining the position of the instrument.

BUSHING PIVOT HOLES, ETC.

=560.= Every watchmaker knows how to proceed in adjusting an ordinary perforated bushing or stopping. We would make a few remarks on the subject of bushings generally.

The tapped bushing is very firm, but, in order that it may be well centered, it is essential that its thread fits exactly the tube of the tool (=322=), and that the pointed rod is exactly central. A turned bushing, especially when a broach can be passed into it after it is in position, is more easily made central (see article =342=).

When bushing holes that are rather large with solid bushings, after the hole has been marked with the pointer it must be drilled with a small drill, a larger one being subsequently passed through, so as to increase it. Otherwise there is great danger of the hole turning to one side.

If a hole, such as that of the center wheel, is bushed with a perforated bushing, it will often be found to incline towards the barrel or fusee, so that the hole is displaced. Such an inconvenience may be avoided by using a bushing with a hole smaller than is ultimately required, afterwards enlarging it with the plate centered in the lathe.

=561.= =Riveting of Bushings.= Some watchmakers have found considerable advantage in replacing the sudden and irregular impacts of a hammer by gradual pressure, without shock, obtained by a small press worked by hand on the principle of a punching machine. With a well made bushing, the flat end of which is slightly rounded, and the inside of the hole in the plate finished with a rat-tail rather than with a cross file, it is found that the riveting is always perfect. Others employ an ordinary pair of sliding tongs, the noses of which are drilled to receive two punches, one flat and the other rounded, as in the mainspring punch. Three pairs of punches suffice for all sizes of bushings, and the same tool can be used for closing up screw-holes, etc.

[Illustration: _Fig. 256._]

=562.= =Movable Bushings.= These are for use in regulator clocks and others of large dimensions, and a few words must suffice for their description. They are the invention of M. Alleaume, and will be understood from Fig. 256. It is always desirable, with a view to prevent wear, that when metal pivot-holes are used, the pivot should bear on a length equal to about three times its diameter; but for such a condition to be satisfied, it is essential that the axes of both holes and pivots be absolutely parallel. The figures will at once show in what manner such parallelism is secured. C C is the plate, in section, in which a hole is made of the form indicated by the lines that bound the cross-hatchings. The movable bushing A is held against a shoulder, and prevented from rotating by a screw, the point of which enters a small hole in the bushing. The pivot of B passes into A, and this latter is capable of such slight motion as will insure contact between the surfaces throughout their length.

DEPTHS.

=563.= =To Secure a Good Depth.= The least skillful of watchmakers can, without much difficulty, place a wheel in the depthing tool in conjunction with a pinion, and change this latter until the two are found to run easily together. But there are comparatively few that are sufficiently acquainted with the subject of depths to be able to select a pinion whose proportions are such as to satisfy the greatest number of the conditions to be fulfilled by a good depth.

This unsatisfactory state of things is due in great measure to the employment, without any correction, of tables of the sizes of pinions (=544=), according to which these sizes are determined by a measurement on the teeth of the wheel, taken with a pinion caliper. This method, although sufficient for ascertaining the size approximately, and even for securing a depth that runs more or less easily, cannot be accepted as an unvarying rule.

Far from resting on any mathematical law, as ignorant men urge in their attempt to instruct others, it is only true for a particular number and form of tooth in regard to the wheel, and a definite thickness of leaf and shape of the rounding in regard to the pinion. It ceases to be true if applied to other numbers of teeth, or to pinions that have their leaves thicker or thinner, or the roundings different from those of the pinion first determined upon.

=564.= _Theoretical and practical depths._ The fundamental principle of every depth is as follows: To determine what curvature should be given to the teeth of the wheel which drives, in order that the tooth that follows (whether its side be straight or formed according to a pre-determined curve) shall be driven in such a manner as to secure the best transmission of force, a transmission which is in part influenced by the uses to be made of the machine.

=565.= Teeth formed like the involute of a circle have very marked advantages, but they cannot be adopted in practice, especially in the case of the leaves of pinions. The epicycloid can be realized very approximately in the teeth of wheels in horology, and such teeth can be used in conjunction with pinion leaves having straight faces, the construction of which does not present any difficulty. This explains why the epicycloidal form has been adopted by watchmakers; but, although it is more easily drawn than the majority of other curves, there are still some obstacles in the way of its general application, mainly dependent on industrial requirements. The difficulty is usually got over by forming the tooth according to a circular arc, nearly identical with the epicycloidal curve, see articles (=440-42=).

=566.= When two mobiles are of the _same diameter_, the theoretical depth will be characterized by having teeth and spaces of equal width; but, since in practice the friction with such an arrangement would be excessive, owing to its taking place on both sides of the tooth, the teeth of the wheel that are driven are so far reduced in thickness as to secure the necessary freedom.

=567.= When the two mobiles are very highly numbered, the lead is short, so that the tooth of the wheel may be a trifle broader or narrower than the space without inconvenience.

But when using pinions of low number (from 6 to 10 leaves), this is not the case. In proportion as the width of the wheel tooth is reduced, its ogive becomes shorter, and the most advantageous portion of the lead (that beyond the line of centers) becomes less. And, besides this, account must be taken of the slipping towards the end of the lead, and the reduction in the difference between the geometrical and the total diameters of the wheel.

=568.= To secure a good depth with low numbered pinions, the leaves should not be more than half the thickness of the space. If they are thicker than this, it may be found necessary to reduce the width of the wheel teeth, when the pitching is insufficient; but the most serious objection lies in the fact that the pitch circle of the pinion will be diminished in diameter. Let there be two pinions with circular roundings and of the same total diameter, but having leaves of different thicknesses—that with the leaves thick will be found to be too small, etc.

=569.= =To Calculate the Vibrations of a Pendulum or Balance.= Multiply together the numbers of teeth of the wheels, starting with the one that carries the minute hand (which therefore makes one revolution in an hour), but exclude the escape-wheel.

Multiply together the numbers of leaves of the pinions, commencing with the one that engages with the center-wheel.

If the first product be divided by the second, the number obtained gives the _number of revolutions_ of the escape-wheel in an hour.

Multiply this figure by _twice the number_ of teeth of the escape-wheel, and the product is the _number of single vibrations performed by the balance or pendulum in one hour_.

ON THE APPLICATION OF THE GEOMETRICAL LAWS OF DEPTHS TO PRACTICE.

=570.= It has been urged that when the geometrical forms of the leaves and teeth, as given in scientific treatise, are accurately carried out in practice, the depths are found to be unsatisfactory and liable to cause occasional stoppage; and these facts are brought forward as evidence that theory and practice are at variance.

On the contrary, theory and practice are in perfect accord: the apparent disagreement arises from an error in the application of the geometrical laws.

In copying the theoretical forms of the teeth of wheels and leaves of pinions, it would be necessary to ascertain that they were mathematically exact, and this is impracticable. Two conditions must be borne in mind:

1. Theory shows that the mobile which drives should be made a trifle larger than the geometrical size, so as to counteract imperfections in the workmanship.

2. A pinion is _never_ made of the exact mathematical proportions, in consequence of the processes that have to be adopted for cutting, polishing, centering, etc. If a number of pinions be taken, and if the several dimensions of each be determined by means of a micrometer measuring to hundredths of a millimeter (or from two to three-thousandths of an inch), differences that are, comparatively speaking, large will be found in the diameters, measuring between corresponding leaves; in the thickness of leaves; in the diameters of the circles at which the roundings join the straight faces, and the general truth of the pinion will nearly always leave something to be desired. It should be added that these faults will be more marked according as the leaves have been more quickly made.

The teeth of wheels will be found to be characterized by similar faults, although they are less marked.

=571.= It follows from these facts that, in watches and timepieces, the _pinion is always a little smaller_ than theory would require; thus the epicycloid should be struck with a somewhat smaller generating circle, and the ogive of the tooth will be proportionately reduced.

The _practical conclusion_ at which we arrive, then, is as follows: As it is impossible to secure absolute perfection in the teeth of small horological mechanisms, their ogives must be slightly more rounded at the points than the designs given in scientific treatises indicate, since these latter are drawn exactly in accordance with the geometrical laws.

These remarks are of the greatest possible importance to the manufacturers of both watches and timepieces; they point to the fact that not only the ogives of all wheel teeth should be lower than theory indicates, but also that, in commoner work, they must be still lower, according as the pinions are of more inferior quality.

=572.= =To Alter a Stem Winding Pinion Depth.= The depth of the Stem Winding Wheel and Pinion often occasions considerable inconvenience, and its adjustment requires to be accurately made: when the depth is too deep, its alteration is easy, as the roundings of the pinion leaves can be reduced, or the stud or other piece that carries the winding wheel can have its base a little reduced on one side, so as to set the wheel a trifle out of upright (but so slightly as not to be perceptible to the eye, and taking care that the teeth remain on a level with those of the barrel-arbor wheel). A shallow depth is somewhat more difficult to correct. If a sufficient change cannot be made by altering the support of the winding wheel, one of the following methods must be resorted to:

1. Reset the pendant of the case.

2. Make a new winding pinion of greater diameter, increasing the number of its leaves by one, to correspond to this change.

3. Alter the position of the movement in the case.

The two first methods are more especially applicable to new work, while the third is more convenient for repairers, although of course it can only be resorted to with advantage when the pinion has a bearing in the pendant. The requisite change in the position of the movement can be produced by raising the rim of the case that supports the plate, or by soldering two thin strips of metal on this rim, producing a similar effect; one on either side of the pendant will suffice, except when a considerable change is necessary,

in which case they should be set at intervals around the rim to avoid an obvious inclination of the dial. Or four holes can be drilled at equal distances apart around the edge of the plate and in its plane, so that their edges overlap the position occupied by the rim of the case; pins are then set in these holes and filed away until they produce the requisite amount of elevation. Or, again, flat-headed screws may be fitted around the edge with their axes at right angles to the plane of the plate and their heads on the dial side.[7] The depth will then be adjusted by screwing these screws more or less into the plate.

It is advisable to ascertain that the dial is not forced too near the glass, as such is occasionally found to be the case, necessitating the bevelling of the edge of the former.

PALLETS.

=573.= =To Advance a (visible) Jewel in a Pallet.= Workmen that have had much experience of escapement making do this without any difficulty by holding the pallet arm in a pair of tweezers that have been slightly warmed, but ordinary repairers will not succeed with such a method: they can however, effect the required change as follows.

[Illustration: _Fig. 257._]

Make a small brass plate, E, fig. 257, with a piece _c_ projecting upwards, which the screw _v_ traverses with stiff friction. A saddle _b_ is fitted to the edge of the plate by screws. A glance at the figure will suffice to show the mode of using it; the pallet arm whose jewel is to be adjusted is clamped under _b_ with the jewel just opposite the screw _v_. Now turn this screw until it stands at the distance from the impulse face of _a_ through which the jewel is to be advanced; taking the plate in a pair of long-nosed pliers, hold them over a small lamp flame, and press with a small screwdriver lightly against the point _a_ so as to advance the stone by the requisite amount as soon as the shellac is sufficiently soft. A particle of shellac is placed at _a_, if any cavity forms during the process, and the plate is laid on some cool body, avoiding contact with the pallet-staff.

If the stone projects below the lower surface of the pallets, a small washer must be placed underneath before clamping the screws of _b_, of such a thickness that the stone is just on the level with the surface E.

=574.= =To Alter the Form of a Pallet Face.= Workmen that possess the requisite skill and steadiness of hand can alter the form of a pallet jewel, when it is necessary to modify the height or form of the impulse face, by simply using a copper polisher charged with diamond powder. The polishing material employed is always decanted in very pure oil, as otherwise it is apt to scratch instead of polish. The coarser quality is first used when a material change has to be effected, but if only a very slight alteration is necessary, and the adjustment has to be very exact, only the finest quality must be used, as there is a danger of making scratches that would be very difficult to erase. We would also add that this operation requires some skill and patience.

[Illustration: _Fig. 258._]

=575.= =To Measure the Lift and all other Angles, etc. of the Lever Escapement.= A very simple instrument for measuring these angles was designed by Curzon, one which any watchmaker can arrange for himself, and is quite sufficient for all practical purposes. This is shown in Fig. 258, and consists of an ordinary depth tool to which a scale is added. A hand adapted to the pallet-staff supported between one pair of runners of the depth tool gives motion to a curved rack (shown by dotted lines), and this causes a pinion carrying a second index to rotate, the radii being so related that the movement of the staff is magnified four times on a scale which can be observed while the glass is at the eye examining the pallets. The index which travels over the shorter scale to the left (divided up to 10° on either side of zero) is connected with the pallet-staff by a fork and a short arm passing through the circular groove; it affords a convenient means of moving the pallets while testing them, and gives a measure, in degrees, of their motion. The graduated arc shown at the top is for measuring the lever and roller.

=576.= =Verge Pallets: to Measure their Opening.= The little instrument shown in Fig. 259 may be used for this purpose; its mode of action will be easily understood from an inspection of the figure.

[Illustration: _Fig. 259._]

One of the pallets being held with its flat face against the base of the graduated semicircle by the lever and spring B, so that the axis of the verge is at right angles to the plane of the instrument through the point _n_, an index previously fixed to the other pallet will show by the graduations the number of degrees of opening.

This index, shown at P, Fig. 160, must be very light. It is formed in two parts, the body _c d_, and the small spring _z z_. The pallet when held in the notch _c_, must have its face held flat against _c d_ by the spring _z z_. The face _c d_ of the index must be quite smooth and straight, so as to avoid any error in the reading of the scale.

[Illustration: _Fig. 260._]

The pressure-block C, Fig. 259 (shown in plan and elevation at C, Fig. 260), is movable on its center, and this center, which by an engraver's error is represented on the line _n r_, should be a little to the right of that line.

=577.= =To Open or Close Verge Pallets.= Some workmen cut a notch at the end of a small rod in which the verge is inserted, the two arms of the fork being then drawn together by a screw; then, holding each pallet in a pair of long-nosed pliers, one in each hand, the rod is held in the flame of a lamp and, as soon as the body of the verge becomes blue, it is gently twisted to the right or left according as the pallets require to be opened or closed.

This method is not always convenient, and the following may be recommended:

[Illustration: _Fig. 261._]

Support the verge by its shoulders between two cone-plate centers in a pair of finishing turns, as seen in Fig. 261. A carrier _b_ is screwed to the upper pallet, and prevents the verge from rotating; _c_ is a rod through which heat is conducted; _a_, shown both in plan and elevation, is another rod, which is much longer than _c_, and has a notch cut at the end, so that it can be forced on to the lower pallet. The end _d_ is free, and the =T=-rest shown dotted at _s_, must be brought nearly into contact with it, the distance between them corresponding to the angle to which it is required to alter the opening of the pallets. Now hold a lamp under the free end of _c_ and, as soon as the body of the verge changes color, _d_ will descend by its own weight until arrested by _s_, the opening will thus be increased or diminished to the requisite extent.

The operation will be accomplished more quickly by directing the blow-pipe flame against the verge body.

Of course when diminishing the opening, the verge must be held in the reverse direction to that shown in the figure.

CYLINDER.

=578.= =To Polish the Cylinder Lips Mechanically.= The polishing of the lips of a cylinder is one of the most delicate operations that can be undertaken by a watchmaker; we have, therefore, endeavored to devise an instrument by which this can be done mechanically, and which should at the same time be so simple and so easily made that any watchmaker should be able to construct it for himself.

[Illustration: _Fig. 262._]

=579.= It consists of two distinct parts which take their place in an ordinary pair of finishing turns. 1. The plate P, Fig. 262, supported on a rod T, to take the place of the =T=-rest. 2. The frame E, whose axis replaces one of the runners. This much being clearly understood from the figure, there will be but little difficulty in understanding the following details.

[Illustration: _Fig. 263._]

On the plate P is mounted a bracket, _b b b′_, held by a screw and washer. It has a slot cut lengthwise, so that on loosening the screw it can be made to slide towards the right or left. The vertical portion _b′_ supports a fork-shaped piece, _d c_, a front view of which is given in Fig. 263, pivoted on a collet-screw, _f_, and this may be fixed by a pin passing through its end like a bolt. The upper end of the fork-piece is provided with teeth for a purpose that will be presently apparent.

The long spindle, _g h_, turns between the two supports, _k_, _l_, fixed to the plate P, under the action of the handle M. This axis carries two eccentric cams, _q_ and R. When it rotates, the eccentric R causes the fork _d c_ to rise and fall, thus occasioning an oscillating movement of the rack _d_, at the same time the other eccentric _q_ presses against the back of the slide _i n_, which moves freely in the guide _s_, and is always held against the cam by a helical spring _j_; the slide thus has an oscillating motion in the direction of its length.

[Illustration: _Fig. 264._]

All the details in regard to the slide and its guide will be easily gathered from the plan in Fig. 262, and the side elevation in Fig. 264.

A small iron polisher is adapted to the slide _n i_. Being pivoted on a pin at one extremity, serving as an axis, its end _u_ is pressed downward by the light spring _v_ (Figs. 262 and 264), which might be replaced by a spiral spring below the polisher if preferred.

=580.= This being understood, we will pass to the frame E.

The rod that carries it is formed of thick drawn steel pinion wire, the diameter of which is less than that of the hole in the poppet-head of the turns. This spindle is provided with brass collars at _y_ and _z_ of such an external diameter as to be received in the poppet-head, in which the rod can rotate freely. By adopting this arrangement, not only is the frictional surface diminished, without reducing the accuracy of the adjustment, but the apparatus can be easily adapted to any pair of turns.

[Illustration: _Fig. 265._]

To the right-hand side of the frame is fixed, by two screws, the cylinder carrier _x_ shown at X, Fig. 265. It must be removed in order to set the cylinder in position by cementing its balance to the surface; care is necessary to make sure that the back of the cylinder shall be towards the side _e_ of the frame when the carrier is again screwed in position. After having thus replaced it, set the rack _d_ to engage with the pinion wire _z_, in such a manner that, when the eccentric cam R occupies the position indicated in Fig. 263, the small iron polisher rests at the middle point of the cylinder lip. Now finally clamp the screw that fixes the support T.

The mode of action of the machine will be easily understood. If, after charging the polisher with polishing rouge the handle M is rotated, the cam R will impart an oscillating angular movement to the frame E through its axis _y z_, and the cam _q_ will, at the same time, cause the polisher to move backwards and forwards, always in contact with the surface of the lip during its movement.

=581.= The work will be performed more rapidly, and the polish will be better if the iron have a slight lateral motion as well as that in the direction of its length. It is, however, more simple to communicate a longitudinal oscillating movement to the cylinder, and this answers the same purpose; it is only necessary to make two small additions, the spiral spring _o_ and the little cock _a_. The latter is fixed to _d_ in an inclined position (as indicated at A), and this inclination can be varied by merely turning the left-hand screw. It will be evident that when _d_ is ascending, the cock will push the spindle _y z_ forward; and when _d_ descends, the spindle will be brought back to its initial position by the pressure of the spring _o_, which is simply placed over the end of the opposite runner. This longitudinal movement must be but slight, and it can be made as little as desired since it depends solely on the inclination of _a_.

=582.= _Observations._ 1. The angular motion of the frame E must be sufficient to enable the polisher to act on the entire surface of the lip. The extent of this movement is determined by the size and the degree of eccentricity of the cam R. The greatest motion will occur when the spindle passes through the hole 1 (Fig. 263), and it will gradually become less as the holes 2, 3, etc., are used. The cam _q_ should also have two or three holes for varying its eccentricity. These cams may be made of hard wood, ivory, etc.

2. The iron polisher may be replaced by a piece of flexible spring fixed by a screw to the slide; but its pressure is less uniform.

3. The bent arm _w_, Figs. 262 and 265, is clamped to the plate P by a screw _d_, and the long arm _b_, Fig. 265, bears against the back of the poppet-head, and thus ensures the steadiness of P. To insure steadiness by its means, _b_ is drawn back in the direction of the arrow, then hooked behind the poppet-head and clamped by the screw _d_. The firmer the support is the better.

4. The machine may be arranged so that the two lips can be polished at the same time, but it then becomes more complicated. In the tool here described, as soon as one lip is polished the cylinder carrier is unscrewed, turned around, and screwed against the left arm of the frame E, in which are two screw-holes opposite to those in the right-hand arm. Unscrewing the slide _b b_, the =T=-rest carrier is moved along the lathe bar until the polisher is over the lip; _b b_ having been set in position is clamped, and, after seeing that _w_ has a bearing, the second lip may be polished.

5. The cylinder carrier shown at X, Fig. 265, is used when the balance is in position. For a plain cylinder without its balance another form of carrier is employed that has at the edge of its central hole a small but solid projecting shell to which the cylinder is cemented.

=583.= _Methods of Obtaining Continuous Motion._ Rapid work is not possible when a single handle, as shown at M, is used for working the apparatus; recourse may, however, be had to one of the following methods:

1. Mount a small pinion with a square hole at its center, and make it engage with a large wheel driven by a handle. This wheel, having a great number of teeth, will proportionately increase the rate of motion.

2. Take a powerful clock movement and connect up its center arbor with the axis _g h_; having wound up the main spring, allow it to run down so long as it possesses sufficient power to drive the mechanism.

3. Fix a ferule at _h_, and drive it by the aid of a foot-wheel.

BALANCE SPRING.

=584.= =To Select a Balance Spring.= Various methods are adopted for this purpose. The most common, by which the strength is ascertained from the length of cone formed by hanging the balance from the inner coil of the spring while the outer is held in a pair of tweezers. A more exact method, based on the same principle, is to employ the small gauge shown in Fig. 266.

[Illustration: _Fig 266._]

A vertical pillar _n n_ is fixed on a smooth plate B, and the slide C is held by friction in any position on _n n_. Place C so that the distance between _c′_ and B is equal to the distance between the end of the lower balance-staff pivot and the balance-spring collet. Having now fitted the spring in this collet, raise the balance, by tweezers holding the outer coil, until the lower pivot just rests on B. The graduations on C will then afford a measure of the extension of the spring, and this extension should about equal the radius of the balance measured on the same scale.

When the number of vibrations performed in an hour is known, a spring may be selected by fitting it to the balance and, while holding the outer coils in the tweezers, supporting the lower pivot on a hard smooth surface; the balance is then made to vibrate and the vibrations are counted. The spring need not be pinned into the collet, but may be attached by wax to the top pivot.

=585.= =To Fix a Balance-Spring to its Collet.= A common way of doing this is to put the collet on a wire or broach which is held in one hand while the other presents the inner end of the spring, held in tweezers, to the hole in the collet; subsequently fixing it with a pin. The following is a more convenient method:

At the middle of a brass plate is a boss tapped through a vertical hole in its center to receive a small screw with flat head. When the collet is fixed by this screw passing through it, the operation of setting the spring in position and pinning it will be much facilitated, and the plate will at the same time afford a means of testing its parallelism. Two or three screws with heads of various sizes should be provided, and, in order that they may be always available, they should be screwed into holes at a corner of the plate.

This tool might be made of further use by adding an arrangement for holding the stud while drilling it, with a view to ensure that the hole is at the proper height.

[Illustration: _Fig. 267._]

=586.= =Balance-Spring Gauge.= A back view and side elevation of this are shown in Fig. 267; it can be made without difficulty by any watchmaker.

Through the middle of the plate passes a staff _a b_ lightly pivoted between the cock _p_ and the plate, and projecting on the left-hand side as far as the point _a_. Between the cock and plate it carries the collet of the spiral spring _s_ and the stop-finger _d c_, and at the point _z_ is a light finger _y z_ that passes over the graduations on the dial.

When the stop-finger _d c_ is free it stands in the direction of the dotted line _i_; on rotating the staff, by taking hold of the pivot _a_, in the direction of the arrow _i_, the extremity _c_ of the finger will be brought round till it presses against the inclined plane _r_, which it will force back and, on coming against the stop near _c_, it will be held fast in the notch of the small bent lever that terminates at _r_. A spring maintains this lever always against a pin set in the plate. The index finger _y z_ will now be standing over the zero of the scale, and will be maintained in that position until the finger _d c_ is released by a momentary pressure of the hand on the push-piece _n_, when it will fly back to the initial position corresponding to the dotted line _i_.

=587.= The instrument is used as follows: The small sliding holder H, which is shown in section at E, (both of these figures being much enlarged since it is extremely fine and light), has a hole through its center that fits on to the axis at _a_. Having set a balance spring in the clip as indicated at E, place H on the pivot _a_, tightening the slide so that it can be used to rotate _a b_, and bring the

stop-finger round to the position _d c_. Holding the outer coil of the spring in tweezers at _v_, its inner coil being held in the clip, release the bent arm by means of the push-piece _n_. The point on the dial at which the finger _y z_ is arrested will give a measure of the force of the balance spring _v_.

It will be evident that a spring can now be easily selected of the same strength as _v_, or stronger or weaker within definite limits which will become well known when some use has been made of the instrument.

The entire mechanism is enclosed within a box that is covered by a glass, through the middle of which a hole is made for the passage of _a_. The spring _s_ is of about the strength ordinarily used for 18-line watches.

[Illustration: _Fig. 268._]

=588.= =To Set a Breguet Spring in Position.= To test the strength of a flat spiral spring that is to be formed into a Breguet spring, it must first be attached by its collet to the balance-staff. As the outer coil cannot be held in the stud owing to its being so near to the pivot hole, it must be held in the clip _b_ of the little appliance shown at S, Fig. 268. Holding the watch-plate between _a_ and _c_, the arm D can rise or fall on the rod _h_, and _b_ can be brought to such a position that it grips the spring at a point just beyond the stud, so that, when the spring is turned inward, the point held may be brought up to the stud. The springing of the watch can thus be proceeded with, and springs tried until one of the required strength is obtained. It then only remains to give the spring the double curvature, and to take care that the end of the overcoil is brought sufficiently near to the center.

Since the action of a Breguet spring is more free than that of an ordinary flat spring, the watch may be found to lose slightly; it is advisable therefore to time the watch before making the bend, so as to show a gain. A little experience will enable the watchmaker to avoid being much out, and any trifling error that there may be is corrected either by a displacement of bend or by altering the central coil. If the latter method is to be resorted to, it is better that the watch should lose rather than gain a little.

=589.= =To Flatten an Ordinary Balance Spring.= Remove the collet and stud, and clamp the spring by a central screw between two plates, which are then placed on a blueing tray and gently heated. A small piece of whitened steel is laid on the plate in order to see that the heat does not exceed what is needed to give a blue temper. Allow the plates to cool and separate them.

Ordinary springs being made of rolled steel and subsequently coiled, always open out on heating; it is therefore necessary before resorting to the above method, to coil up the spring, as otherwise the outer turn will be found to have opened beyond the stud.

=590.= =To Diminish the Strength of a Balance Spring.= Scraping the end or the entire length always renders the spring defective. Dipping in acid is very little better. It is preferable to embed the spring in cork or soft pith, and work it over a ground glass plate covered with oil stone dust that is fine and smooth. This method might be resorted to for reducing the height of a mainspring.

[Illustration: _Fig. 269._]

If the cork or pith is hard and only a little metal has to be removed, the operation is successful; but it is apt to result in more metal being removed from the edges than from the center. When much has to be removed, the spring must be cemented to the polishing plate (shown at G, Fig. 269, and described in article =345=) with fine wax, thoroughly liquid, so that on pressing the spring all its coils may come in contact with the plate; it must be held thus until cold. Now adjust the leveling screws, so that the whole surface bears flat on the glass; rub it as long as is considered necessary, and detach the spring as soon as the plate is sufficiently heated; boil in alcohol to clean its surface.

=591.= =To Harden Gold Springs.= Gold detent, thermometer, suspension and balance-springs can be obtained of a high degree of elasticity. Rolling hardens them, but renders them very brittle. They can be made supple and elastic, not by hardening, as in the case of steel, but by annealing, care being taken not to exceed a certain degree of heat. The spring may be coiled on a block and placed in a tube that has a smooth steel lid, then heat the tube in the flame of a spirit lamp, and as soon as the steel is of a blue temper, remove the flame and allow the whole to cool.

Others anneal by keeping the spring in boiling oil for a definite period.

The hardness of a gold spring increases with the proportions of alloy it contains, and, if well annealed, it will be very elastic and will break when bent too far, as in the case of steel.

=592.= =To Ease an Index on Its Endstone Cap.= It is a common but bad practice among watchmakers to scrape the inside of the ring of the index or to cut it through. A better method is as follows: Resting the index on a cork, cover the inside of its ring with oil stone dust and make the cap rotate in its seat by means of a pinion calliper, the two points of which are inserted in the screw-holes. The operation is repeated as often as may be required.

DIAL PLATE.

=593.= =To Cut the Large Hole in the Timepiece Dial Plate.= Some workmen cut the hole in the dial-plate of a timepiece by means of a strong pair of compasses, one leg of which terminates in a bullet-nose that is supported in a central hole, while the other is provided with a hardened cutting point that serves to scrape out a groove.

Others use a rule that revolves on a conical point and carries a slide with a tracing point which can be replaced by a sharp-pointed cutter. Proceed in exactly the same manner as when using the compass, but a greater force can be applied, because, while one hand steadies the center, the full force of the other is applied to the cutter.

A third and still simpler plan is adopted by some clockmakers. A rod of the diameter of the central hole, and a cutter of which only the cutting point projects, are gripped in a vise at a distance apart equal to the radius of the hole to be made. Then passing the rod through the central hole and holding the plate in both hands, rotate it, at the same time applying pressure so as to cause the cutter to form a groove. When a moderate depth has been attained, invert the plate and cut one on the opposite side. Care is necessary when the grooves are on the point of uniting; on the removal of the center, smooth the edge with a half round file. Some workmen consider it more convenient to set the cutter and rod in a thick piece of wood that is rounded at the top and made flat on its two sides towards the bottom, so as to be firmly held in the vise.

=594.= =To Drill an Enamel Dial.= Take a hard, well-sharpened graver and moisten it with turpentine or turpentine that contains camphor in solution, or in the following mixture, which is still better:

Turpentine 62 parts by weight. Oxalate of potassium 4 ” ” Camphor 4 ” ”

The two latter substances are reduced to powder and dissolved in the turpentine, and two parts by weight of sandal wood may be added.

The graver point is placed on the dial at the point at which a hole is required and the graver is rotated backwards and forwards between the fingers. Practice, acquired by drilling a few holes in broken dials, will soon indicate the degree of pressure that can be applied without fear of accident. Some workmen prefer only to apply the maximum pressure while the graver rotates in one direction, reducing it during the opposite movement; others hold the handle or tang in one hand and rotate the graver with the other, always in the same direction.

The operation is continued, frequently arresting it, however, in order to set the graver and moisten it, until the copper-plate and back enamel are perforated.

As soon as this point is reached, take an iron or steel spindle, pointed at one end. The point must be more obtuse than the hole already formed in the dial. Charge this end with emery or oilstone dust, and place in the chuck in your lathe; when the spindle is caused to revolve the enamel on the contour of the hole will be rapidly removed. When the copper disc is reached, a fine-pointed and sharp graver must be used to remove the metal that is exposed as well as that which is covered with only a thin layer of enamel; then renew the operation with the spindle, occasionally drawing a file along the surface of the acting cone. Or the cones of solid emery to be obtained at material stores can be used for this purpose. A workman must be very careless or unskilful to fail in rapidly drilling a hole in a dial by this method without accident, and he may carry on the process easily until the hole is large enough to permit the introduction of a rat-tail file.

=595.= =To Enlarge a Dial-Hole With a Rat-Tail File.= As an extra precaution the contour of the hole on either side may be coned with a spindle as explained above, so as to reduce the thickness of enamel to be acted upon by the file; but a watchmaker that has had any experience can dispense with such a preliminary, which we would at the same time recommend.

The file must enter the hole freely. If only the point can do this, the file must be held very short, so that the finger may come in contact with the dial before the larger diameter of the file locks in the hole, as this would almost certainly crack the enamel. Some workmen avoid such an accident by forcing on to the file a rather long cork of small diameter.

With a view to avoid scratching the face of the dial in case the file is drawn out of the hole in its backward movement, it is well to round off and polish its point.

During the forward movement a slight circular motion is given to the file, and in returning no pressure is to be applied; the file must merely slide over the surface. It is dipped from time to time in the liquid mentioned in the last article. When the hole is large enough, a conical spindle should be used to smooth its edges as in the earlier stages of the process.

=596.= =To Remove Enamel from the Back.= To remove portions of the enamel from the back when it touches part of the motion work, etc., various methods are adopted.

The little spindles of solid emery that may be obtained at material stores may be used for the purpose.

Some watchmakers use a flattened lead ball perforated at its center and carried on a taper arbor, forming a kind of small grindstone, rounded across its rim. The arbor is held in a chuck and the edge of the lead disc is moistened with water, and emery powder sprinkled over it; when set in rotation the surface to be removed is held against the lead, the necessary pressure being applied by the finger against the other face. Water must be frequently sprinkled on the surface so as to avoid heating, and to maintain the emery in its place, and the dial is washed occasionally to examine the progress of the work.

In place of lead, some use emery formed into a solid block with shellac or various kinds of cement; it is centered on a large taper arbor, and should be at least a quarter of an inch thick and rounded at its edge. Such a disc is very hard when cold; it is used in the manner explained in the last paragraph, but wears more rapidly than the lead disc, if the latter is well made and supplied with emery of the right degree of coarseness, in sufficient abundance and evenly distributed.

=597.= =Dials Fixed by Screws through the Edges.= The screw-holes at the edge are drilled in the manner already explained in article =594=, and the center hole is enlarged as there described, if this is found to be necessary in order to permit the free passage of the hour wheel. The diameter of a dial may be reduced if it is too large in the manner explained in article =600=. When it has been thus prepared, place it in position, the XII being exactly opposite the pendant, with the movement in the case, and close the bezel. If the dial is found to shake under the bezel it should be fixed with three or four small wedges of pegwood, care being taken that they do not subject the dial to much pressure. The accuracy of the position may be tested by holding a stretched piece of cord over the dial, and observing whether it passes at the same time through the middle of the pendant, the center hole, the XII and the VI. When the dial is thus found to be properly placed, mark one of screw-holes on the watch-plate through a dial-hole. Some care is necessary in doing this lest the hole is marked eccentrically or the dial is displaced by pressure against one side of the hole in it, which might result in the dial being cracked by the screw. Now remove the plate from its case and drill its screw hole in the drilling tool; tap it and fit the screw. Replace the plate in the case, and, after fixing the dial to it with the one screw thus fitted, carefully mark the second hole, etc.

Some workmen expedite the operation by marking and drilling the two holes at the same time; but if at first they do not succeed in making them in the required position they materially increase the time occupied, as one hole at least requires to be bushed, etc.

=598.= =Dials Held in Position by Feet.= If the dial has feet, and it is required to adapt them to the plate, they must be first carefully bent straight; then take a piece of stiff card board of moderate thickness, and laying it on a piece of lead, punch out with a sharp-edged punch, or other means, a round hole of the diameter of a foot. Having inserted one foot in this hole, and placed the card on a flat surface with the dial uppermost, apply a slight pressure to this latter so as to mark the position of the second foot. Then punch out a second similar hole at the point thus indicated. If the operation has been properly conducted the two feet will enter the holes easily, but at the same time without constraint or shake, and they should project on the opposite side.

It now only remains to cut out the cardboard to the size of the plate, and, after making a central hole and a mark to exactly correspond with noon, to place it in position in the frame and under the bezel, as though it were the actual dial. Then mark the two holes for the dial feet, using a sharp-pointed chamferer that just fits the hole, held vertical and rotated by one hand, while pressure is applied by a finger of the other hand.

Some workmen merely prick holes in the card with some sharp-pointed instrument, or even force the feet through it at all risks; hence it happens that feet are often bent out of the vertical, and, in order to be able to bend them into the required position, it becomes necessary to enlarge the holes in the plate and bend the dial feet.

[Illustration: _Fig. 270._]

=599.= =To Cut a Large Hole in a Dial. To set a Seconds Dial.= This operation is performed in the ordinary lathe. The hole is cut by a ring of thin iron or copper cut with saw-like teeth round its edge, as shown at V, Fig. 270, kept in rotation and charged with fine emery and oil or water or, what is better, turpentine. The mixture described in article =594= will secure a still more rapid action.

It is advisable that the thickness of the ring be made to gradually diminish from _e_ towards _i_, as indicated by the section at S, so as to prevent it from choking and probably cracking the dial.

The following arrangement may be adopted: Prepare a strong ring with a projecting internal ridge, shown in section at A B C; cement the dial, _g d_, to this ridge, or fix it by any convenient means, and attach this supporting ring to a chuck that rotates in a direction opposite to that of the cutter, but much less rapidly. On reaching the copper disc, reverse A B C and repeat the above process on the back enamel. The copper is thus exposed on the two sides. On filling the deeper groove with dilute nitric acid the metal will gradually be eaten away, and the acid should be renewed as often as may be needed. It then only remains to smooth the edge, beveling it on the front side, and to cement the seconds dial in position.

The use of acid may be avoided and the cutter passed through the copper, but greater care must be exercised, because the work is more difficult when operating on metal. It will, however, not be difficult after a few trials.

Willis recommends that the dial be cut straight through, commencing at the back and using emery and oil, the dial being cemented on a brass block immediately below the cutter, and rather less in diameter than the hole produced. He mounts the cutter on a stock that is provided with a pump center, the point of which is maintained throughout the operation in the small hole or point that marks the center of the hole. The great advantage of this method is that the taper of the hole is in the required direction and no filing is necessary.

=600.= =To Reduce the Diameter of a Dial.= Resting the dial in an inclined position against a block, file its edge with a smooth or half-smooth file, which must only be allowed to act while advancing, and is at the same time displaced sideways and turned so as to follow the contour of the dial. The file should be dipped occasionally in turpentine, and when sufficient enamel has been removed, pass a new emery stick over it to remove the file marks.

=601.= =To Remove a Figure or Name from a Dial.= Oil of spike lavender may be employed for erasing a letter or number.

Enamel powder made into a paste with water, oil, or turpentine, is also used for this purpose. It should be previously decanted so as to obtain several degrees of fineness. The powder used for re-polishing the surface where an impression has been removed must be extremely fine. It is applied on a piece of pegwood, although some use ivory.

The last and best system is to use diamond powder. Take a little of the powder, made into a paste with fine oil, on the end of a copper polisher, the surface of which has been freshly filed and slightly rounded. On rubbing the marks they will be seen to rapidly disappear.

The surface is left a little dull; it may be rendered bright by rubbing with the same powder mixed with a greater quantity of oil and applied with a stick of pegwood.

Watchmakers will do well to try several degrees of fineness of the diamond powder on old dials.

METAL DIALS.

=602.= =To Restore a Silver Dial.= We proceed to describe several methods of doing this, but would at once observe that when the earlier ones are adopted, the hours, if they are painted, necessarily disappear; whereas they can be retained by resorting to the last method although great caution must in that case be taken; moreover, it is much more difficult to accomplish than the others.

=603.= First Method. This is the most expeditious system, and at the same time the most certain of success.

If the hours are in enamel, there need be no fear; if engraved and filled with black composition, this will disappear, but it can be replaced without difficulty. There remains the case of painted hours to be considered.

First make thin marks with a fine point along the lines of all the figures, taking care not to pass beyond their ends: and do the same for the dots and lines that indicate the seconds. By using a glass and following the instructions given in article =619=, no difficulty will be experienced in doing this, and the fine lines and dots thus made will afford sufficient guide for re-marking the hours.

Begin by cleaning the dial with a brush and fine pumice-stone so as to remove spots and slight scratches.

=604.= _To Frost the Surface._ In order to frost the surface of the dial, take a spirit lamp with large wick, and direct a blow-pipe flame from it against the under side of the dial, which is held by one hand with a hooked support. If the flame is gently directed over the entire surface of the back, a good dead surface is obtained that resists a moderate degree of friction either in soaping with a fine sponge, or washing in a large quantity of water, or in applying soft bread and oil of spike lavender to erase irregularities or marks made in painting the figures.

The application of the flame is several times repeated, so as to obtain a decisive and even frosting; but it is necessary, with a view to avoid buckling the thin metal, to place an iron or copper washer behind the dial. The flame oxidizes the surface of the metal; that is to say, it causes the oxygen of the air to combine with the copper which is alloyed with silver.

=605.= _Pickling or Bleaching the Dial._ Introduce sufficient warm water into a suitable flat vessel to completely cover the dial, and gently pour into it a few drops of sulphuric acid (oil of vitriol), so that the two liquids are in the proportion of about 1 to 10; then lay the dial in this dilute acid for a period that varies from half to one or two minutes. The frosting will first become yellow and then of a beautiful white color. Wash it in a large quantity of water, wipe with a fine linen rag, and apply the flame momentarily to the back in order to prevent the formation of spots on the surface.

When several dials have to be operated upon, the acid is put in a porcelain dish and boiled by a lamp. Then place each dial for a moment in it, wash in an abundant suppl of water, and dry by tapping with a fine linen rag.

=606.= Second Method. For the benefit of such as care to experiment with it, we add the following method: Brush the dial with a coarse brush and pumice-stone reduced to an impalpable powder until no scratches are visible. Make it red-hot and allow to cool. Then dip for two or three seconds in a porcelain vessel containing dilute sulphuric acid; on removal it will be found to be white, but rather dull. In order to produce a clear frosted surface, place the dial in a mixture of

6 parts by weight of nitric acid of 1.22 sp. gr.[8] 21 ” ” sulphuric acid. 50 ” ” water.

Allow the metal to remain in this acid until no more globules are seen to form on its surface, then withdraw it and immediately place in cold water. The dial will be observed to be nearly black; it is then pickled as above explained (=605=), washed well, heated red-hot and, when cold, again pickled; the operation is concluded by thoroughly washing its surface.

=607.= _Third Method._[9] Cover the surface of the dial with a thin layer of soap, and brush it over, taking care to avoid touching the hours if these are not enamelled. This can best be done with a fine brush and pumice stone reduced to an impalpable powder. When the dial has been made as clean as possible by this means, wash it carefully with water and tartrate of potash (cream of tartar), then plunge it immediately in the hot solution of nitrate of silver (=608=) attaching it to the silver wire which is fastened to the zinc and copper discs =609=; in two or three minutes the surface of the metal will be perfectly frosted, and, if each operation has been cautiously performed, the hours will remain intact.

Each time the zinc and copper discs are used they should be cleaned with nitric acid, and rubbed over with pumice stone. As soon as the dial is clean, immerse it in the solution; the least delay is apt to cause the surface to become oxidized through contact with the air.

=608.= _To Prepare the Silver Solution._ Dissolve an ounce[10] of solid nitrate of silver (lunar caustic) in a small quantity of water; filter the solution and add twice its volume of liquid ammonia. In a separate vessel dissolve 6 ounces of yellow prussiate of potash and 4 ounces of crystallized carbonate of soda in 60 ounces of water, contained in a vessel of enamelled iron, which must be placed on the fire. When near the boiling point add the concentrated solution of nitrate of silver, and allow the mixture to boil for an hour, taking care to add hot water in sufficient quantity to make up for that lost by evaporation; then filter the resulting solution.

=609.= _To Prepare the Discs and to Plate._ In order to use this solution for restoring a dial or plating any other object, take two discs about the size of a half dollar, one made of zinc and the other of copper, and, after making a small hole in each, unite them

with a copper wire, or, preferably, with one of silver. After having attached the dial or other object to this connecting wire, immerse the entire system in a glass or earthenware vessel, and pour over it a sufficient quantity of the solution, previously made hot.

If the object operated upon is perfectly clean, bright and free from all greasy or oily matter, its surface will be found in two or three minutes to be covered with a firmly adherent layer of silver. When only a small piece is treated it will suffice to immerse it in the hot liquor, and rub it with the finger; a bright silvered surface will thus be obtained.

=610.= =To Clean Metal Dials of Clocks.= When the hours are neither enamelled nor engraved, it is necessary to first trace out the several lines and dots in a manner similar to that explained in article =619=.

=611.= _Ordinary Mode of Cleaning the Dial._ Very often it is possible to make a silver or plated dial of either watch or clock sufficiently clean by merely brushing with powdered cream of tartar worked into a paste with water, carefully rubbing around any painted figures with a fine stiff brush. Then wash with clean water, dry by gently tapping with a fine linen rag, and expose to a slight heat. (This is in part the same method as is described in article =607=; the two may be combined). If the dial is tarnished, it must be silvered as explained below.

=612.= =To Plate a Brass Dial.= _Preparing the Silver._ Place in a glass flask from 100 to 150 grains of pure silver made into thin strips by means of a hammer or rolling mill. Add five or six times the weight of dilute nitric acid so as to completely cover the silver, and warm the vessel, taking care to avoid breathing the fumes or admitting them to the workshop. The metal will be dissolved, and, on continuing the application of heat until all the liquid is evaporated, crystals will be found at the bottom. When cool fill the flask with warm water and, as soon as all the crystals are dissolved, pour the solution into a porcelain dish, previously half filled with water. Place in it a sheet of clean copper of about the size of three fingers, and allow it to remain for the night.

On the following day all the silver will be found attached to the plate, and it can be collected by immersing this in water. Carefully pour off the water from the fine powder thus obtained, and wash it once or twice with an abundant supply of pure water; then dry thoroughly with the application of very moderate heat. If the silver thus obtained is not required for immediate use, it should be kept in a dark blue bottle to avoid the influence of light and moisture.

=613.= _To Prepare the Surface of the Dial._ It must be quite smooth, thoroughly washed and dried. M. Robert recommends that the smoothing be accomplished by using soft water of Ayr stone, rubbing in all directions, in order remove scratches. Or pegwood charcoal can be used, sloped at one end like a whistle, and applied with water. Others employ pumice-stone powder and very fine emery paper.

=614.= _To Apply the Silver._ Take equal parts of rock-salt and cream of tartar, pound them together, and when well mixed, take about 60 or 80 grains of the mixture, and add to it 15 or 20 grains of silver, prepared as above described, and add a few drops of water to form a thick paste, which must be well mixed and worked up on a ground glass plate by means of a horn spatula to remove all grits. A glass pestle may be used for this purpose.

The dial having been prepared, take up some of the paste with a perfectly clean and rather stiff brush, and spread it over the surface of the dial, rubbing quickly and somewhat harshly. The brush should be worked about in all directions, so as to avoid scratches, until the silver is found to adhere firmly to the dial. According to M. Robert, this rubbing is to be continued until the required grain is obtained; but M. Fournier states that it should be arrested when the surface possesses a lead-grey color; the dial is then well washed, dried, and the operation re-commenced exactly as before except that the brush used is softer. A good surface will thus be formed, and it will be whiter if the proportion of silver in the paste is increased.

The result attained in great part depends on the skill of the operator, and this can only be acquired by experience.

=615.= _Observations._ If the mixture contains too much of the salt or too little silver, the latter will adhere with difficulty, and will come off in lumps or scales; moreover, it will not have so white a color.

As the proportion of silver is increased, the white becomes gradually better; but, on the other hand, if it is in excess the surface will be coarse and uneven. Too much or too little water will have nearly the same effect. The color is worse if the dial has been imperfectly smoothed, and when several days or even hours are allowed to elapse between the cleaning and silvering.

It is essential that the rock-salt and the cream of tartar be perfectly pure; if they contain any earthy matter it will scratch the surface and impair its whiteness.

As soon as the operation is completed, the dial must be washed in an abundant supply of pure water; any neglect in this particular will cause it to blacken. This washing may be performed with an ordinary watch-brush, charged with cream of tartar. Then rinse the dial, and dry, tapping gently with a fine linen rag, and finish by slightly warming it.

=616.= =Gold Dials.= It will not be necessary to say much on this subject. In order to restore the color to a gold or gilt dial, it may be dipped for a few seconds in the following mixture: Half an ounce of cyanide of potassium is dissolved in a quart of hot water, and two ounces of strong ammonia mixed with half an ounce of spirits of wine and added to the solution. On removal from this bath, the dial is immediately immersed in warm water; then brush with soap, rinse, and dry in hot boxwood dust. Or it may be simply immersed in dilute nitric acid, but in that case any painted figures will be destroyed.

=617.= _Another Receipt._ The following is the method ordinarily adopted for coloring gold dials; but it is to be observed at the outset that, although apparently characterized by extreme simplicity, a good deal of skill is needed to ascertain when the mixture is of the right consistency, and when the dial has been sufficiently exposed to its action.

Make a mixture of 4 oz. saltpetre, 2 oz. alum and 2 oz. common salt (the purest attainable), with a very little water. On placing this in a blacklead crucible over the fire it will become limpid, and must be allowed to boil until somewhat pasty and of a pale yellow color, stirring all the while with a stick. Now take two dials, back to back, that have been cleaned and blackened by annealing, and pass a platinum wire through their centers so that they hang horizontally, resting on a loop at its end; immerse the dials in the hot color crucible, and, after holding it for a short time, withdraw them and immediately immerse in a vessel of nearly boiling water standing close by. The “color” will then be washed, and the progress of the work can be observed. The dials are again dipped in the crucible if necessary, and will probably require about three minutes’ immersion in all. It is advisable that the “color” be thick rather than thin, as in the latter case the dials are apt to be clouded.

=618.= =To Re-Paint the Hours on a Dial.= The following system has reference to metallic dials, but the reader will be able to s

VI. A FEW CULINARY RELATIONS OF CHOCOLATE AND BREAKFAST COCOA, BY MRS. ELLEN H. RICHARDS AND MISS PARLOA 35

INTRODUCTORY.

Four years ago, a convenient handbook on the production and use of various preparations of the chocolate plant was published by our firm. The present work is designed to give, with considerably more detail, some of the interesting facts relative to the early history and cultivation of the chocolate tree, as well as a fuller account of its botany and the chemistry of its products. Since this _brochure_ will doubtless fall into the hands of some who do not have access to the earlier work, we have used with freedom some of the material employed in that; but we hope that these necessary repetitions will increase instead of impair the value of the pages now before the reader.

We trust that this second treatise may be acceptable to our many friends who gave so warm a welcome to the first.

THE CHOCOLATE-PLANT.

I.

OUTLINE OF THE EARLY HISTORY OF THE CHOCOLATE-PLANT.

At the discovery of America, the natives of the narrower portion of the continent bordering on the Caribbean Sea, were found in possession of two luxuries which have been everywhere recognized as worthy of extensive cultivation; namely, tobacco and chocolate. The former of these has made its way into climates totally unlike that of its early home; the other of these plants, since it cannot bear the low temperature occasionally experienced in our subtropics, is more restricted in its range. The chocolate-plant is confined to the warmer regions of the globe, where it finds the congenial climatic conditions which it enjoyed and still enjoys in its earliest home in America.

The first references to the chocolate-plant and its products are found in the accounts of the explorers and conquerors who followed Columbus. These first descriptions of this singular tree, of its fruits and seeds, of its uses and the methods of cultivation, are remarkably accurate in all essential particulars.

[Illustration]

One of the earliest, if not indeed the very earliest, delineations of the chocolate-tree is in a rare volume by Bontekoe. The engraving, which is here reproduced with fidelity, represents the chocolate-tree with its comparatively large fruits or pods borne on the main stem. This might be thought at first to be an error of the artist, but it is in fact a rude expression of one of the most remarkable peculiarities of the plant. As will be shown presently, when a fuller description of the plant is given, the fruits are, as a rule, formed on the older parts. Another interesting feature is shown in the engraving:[1] the chocolate-tree is sheltered by a larger tree of some other kind near it. We shall see shortly, that this practice of planting a sheltering tree to shade the young chocolate plants for a time, is still kept up wherever the plant is successfully cultivated. It is certainly interesting that this point in cultivation, which might easily have been thought to be accidental or local, was delineated more than three centuries ago. By the natives of tropical America, the seeds of the chocolate-plant, which will be more particularly described in a later chapter, were first roasted and then rudely ground. For this purpose they employed the flat or curved surface of the sort of stone used by them to grind their maize, or Indian corn. In the engraving, one of the most simple mills or flat mortars is seen with its roller. The roller was merely a short thick stone of a cylindrical shape, which could be used with one or both hands somewhat after the manner of the common rolling-pin everywhere used in kitchens. By this simple appliance, the crushed seeds were mixed with various ingredients, among which may be mentioned spices of different kinds. A modification of this was later used in Spain. See page 15.

[1] The figure in the left of the foreground is said by Bontekoe to represent the native method of procuring fire by rapidly twirling a pointed stick in a groove of a piece of wood placed on the ground.

[Illustration: FROM A PHOTOGRAPH OF A STONE MILL, OR FLAT MORTAR.]

The drinks made from this coarse chocolate were frequently very complex, but the chocolate itself was the chief constituent. It was the custom to beat the mixture into a froth or foam, by means of stirrers, of mallet-like forms; in fact, it is said by some writers that the very name chocolate, is derived from a native word indicating the noise made by the stirring of the beverage.

Thus, Thomas Gage, in his “New Survey of the West Indies,” says (under date of 1648), “The name chocolatte is an Indian name, and is compounded from _atte_, as some say, or as others, _atle_, which in the Mexican language signifieth water, and from the sound which the water (wherein is put the chocolatte) makes, as _choco_, _choco_, _choco_, when it is stirred in a cup by an instrument called a ‘molinet,’ or ‘molinillo,’ until it bubble and rise unto a froath.”

[Illustration: SOME OF THE FORMS OF CHOCOLATE STIRRERS (“MOLINETS”).

From a treatise published in the Seventeenth Century.]

The same writer gives us an interesting account of the native method of preparing the drink. From the extract, which is copied without change of the quaint spelling, it will be seen how wide the use of chocolate was in Europe towards the middle of the seventeenth century:--

“Now, for the making or compounding of this drink, I shall set down here the method. The cacao and the other ingredients must be beaten in a morter of stone, or (as the Indians use) ground upon a broad stone, which they call _Metate_, and is only made for that use. But first the ingredients are all to be dried, except the _Achiotte_, with care that they be beaten to powder, keeping them still in stirring that they be not burnt, or become black; for if they be overdried, they will be bitter and lose their virtue. The cinnamon and the long red pepper are to be first beaten with the anniseed, and then the cacao, which must be beaten by little and little till it be all powdered, and in the beating it must be turned round that it may mix the better. Every one of these ingredients must be beaten by itself, and then all be put into the vessel where the cacao is, which you must stir together with a spoon, and then take out that paste, and put it into the morter, under which there must be a little fire, after the confection is made; but if more fire be put under than will only warm it, then the unctuous part will dry away. The _Achiotte_ also must be put in in the beating, that it may the better take the colour. All the ingredients must be searced, save only the cacao, and if from the cacao the dry shell be taken, it will be the better. When it is well beaten and incorporated (which will be known by the shortnesse of it), then with a spoon (so in the Indias is used) is taken up some of the paste, which will be almost liquid, and made into tablets, or else without a spoon put into boxes, and when it is cold it will be hard.

“Those that make it into tablets put a spoonful of the paste upon a piece of paper (the Indians put it upon the leaf of a plaintin tree), where, being put into the shade (for in the sun it melts and dissolves), it grows hard; and then bowing the paper or leaf, the tablet fals off by reason of the fatnesse of the paste. But if it be put into anything of earth or wood, it stickes fast, and will not come off but with scraping or breaking. The manner of drinking it is diverse; the one (being the way most used in Mexico) is to take it hot with Atolle, dissolving a tablet in hot water, and stirring and beating it in the cup, when it is to be drunk, with a Molinet, and when it is well stirred to a scumme, or froth, then to fill the cup with hot Atolle, and so drink it sup by sup. Another way is that the chocolate, being dissolved with cold water and stirred with the Molinet, and the scumme being taken off and put into another vessel, the remainder be set upon the fire, with as much sugar as will sweeten it, and when it is warme, then to powre it upon the scumme which was taken off before, and so to drink it. But the most ordinary way is to warme the water very hot, and then to powre out half the cup full that you mean to drink; and to put into it a tablet or two, or as much as will thicken reasonably the water, and then grinde it well with the Molinet, and when it is well ground and risen to a scumme, to fill the cup with hot water, and so drink it by sups (having sweetened it with sugar), and to eat it with a little conserve or maple bred, steeped into the chocolatte.

“Besides these ways there is another way (which is much used in the Island of Santo Domingo), which is to put the chocolatte into a pipkin with a little water, and to let it boyle well till it be dissolved, and then to put in sufficient water and sugar according to the quantity of the chocolatte, and then to boyle it again untill there comes an oily scumme upon it, and then to drink it.

“There is another way yet to drink chocolatte, which is cold, which the Indians use at feasts to refresh themselves, and it is made after this manner: The chocolatte (which is made with none, or very few, ingredients) being dissolved in cold water with the Molinet, they take off the scumme or crassy part, which riseth in great quantity, especially when the cacao is older and more putrefied. The scumme they lay aside in a little dish by itself, and then put sugar into that part from whence was taken the scumme, and then powre it from on high into the scumme, and so drink it cold. And this drink is so cold that it agreeth not with all men’s stomachs; for by experience it hath been found that it doth hurt by causing pains in the stomach, especially to women.

“The third way of taking it is the most used, and thus certainly it doth no hurt, neither know I why it may not be used as well in England as in other parts, both hot and cold; for where it is so much used, the most, if not all, as well in the Indias as in Spain, Italy, Flanders (which is a cold countrey), find that it agreeth well with them. True it is, it is used more in the Indias than in the European parts, because there the stomachs are more apt to faint than here, and a cup of chocolatte well confectioned comforts and strengthens the stomach. For myself I must say, I used it twelve years constantly, drinking one cup in the morning, another yet before dinner between nine or ten of the clock; another within an hour or two after dinner, and another between four and five in the afternoon; and when I was purposed to sit up late to study, I would take another cup about seven or eight at night, which would keep me waking till about midnight. And if by chance I did neglect any of these accustomed houres, I presently found my stomach fainty. And with this custome I lived twelve years in those parts healthy, without any obstructions, or oppilations, not knowing what either ague or feaver was.”

After its introduction into Europe from America, chocolate was used at first only as a luxury, but it has steadily advanced in popular esteem until it is now recognized as one of the necessaries of life.

[Illustration: FRONTISPIECE OF ONE OF THE EARLIEST WORKS ON CHOCOLATE.]

It would be interesting to speculate as to the accidents which led to the original use of such beverages as coffee, tea, and chocolate. The earliest employment of the two former is veiled in as deep a mystery as that which surrounds the chocolate-plant. All were used at the outset by what we have been accustomed to call the uncultivated races of mankind, but we cannot surmise what first attracted their attention to these plants. One can only say that by the natives of lands where the plants grow naturally, they have all been used from time immemorial, and that all three are welcome gifts from a rude state of civilization to the highest which exists to-day. By the savages and the Aztecs of America, by the roving tribes of Arabia, and by the dwellers in the farther East, the virtues of these three plants were recognized long before any one of them was introduced into Europe.

There is reason to believe that long before the discovery of America, Tea and Coffee had been vaguely known to travellers in the Orient, as curiosities, much as we to-day regard the Kola-nut and Maté, but neither Tea nor Coffee was then employed as a beverage anywhere in Western Europe. In fact, all trustworthy evidence in the case leads us to a surprising conclusion, namely, That _Chocolate was the first of these beverages to attract the attention of Europeans_. This beverage rapidly made its way throughout Europe, beginning from Spain and Portugal, whither its discoverers had brought it. The other beverages, Tea and Coffee, soon followed, and after a short time became associated together in popular regard.

In a duodecimo work published in 1685, and now very rare, the beverages derived from these three plants are described in a clear and forcible manner. The reproduction of the frontispiece of this book, given above, shows how intimate the association of these beverages was regarded even two centuries ago. It is interesting to observe the distinction made by the artist in the receptacles and cups for holding these three different drinks. On the floor, near the vase, is seen one of the chocolate-stirrers described on page 10.

At the outset the manufacture of chocolate in Europe was carried on with substantially the same appliances as those used by the natives. A curious indication of this is afforded by the engraving, which shows that the Portuguese mill was to all intents modelled after that used by the Mexicans.

From an early engraving.]

II.

THE NATURAL HISTORY OF THE CHOCOLATE-PLANT.

[Illustration: THEOBROMA CACAO.]

The chocolate plant is known to botanists as _Theobroma Cacao_. The first or generic word in this name means _food of the gods_. The genus contains six species, only one of which is generally cultivated. It is probable, however, that some of the seeds which find their way into commerce are yielded by other and wild species. It is, moreover, more than likely that among the numerous varieties of Theobroma Cacao now cultivated there may be some hybrids between the different forms.

[Illustration: FLOWERS, FRUIT, AND SEEDS OF THEOBROMA.

From an old engraving.]

The plant belongs to the Sterculiaceæ, a natural order containing forty-one genera and five hundred and twenty species. The general habit of the tree is well shown in the engraving.

[Illustration: FLOWERS, FRUIT, AND SEEDS OF THEOBROMA.

From a recent drawing.]

The seeds of the plant are borne in pods, represented in the illustrations on pages 17 and 18, the former taken from one of the early works on the subject. No. 1 in the first engraving exhibits the ripened pod, 5 and 6 the fruits in different stages of growth. No. 2

shows the pod cut open and displays some of the seeds, while 3 and 4 are the seeds themselves,--the former in its natural state, the latter with the seed-coats removed.

The pod is irregular and angular, much like some forms of cucumbers, but more pointed at the lower extremity, and more distinctly grooved. It measures in length nine inches to a foot, or even more, and about half as much in diameter. The color, when young, is green, becoming later dark yellow or yellowish brown. The rind is thick and tough. The pod is filled with closely packed “beans,” or seeds, imbedded in a mass of cellular tissue, sometimes of pleasant subacid taste. The seeds are about as large as ordinary almonds, whitish when fresh, and of a disagreeable bitter taste. When dried they become brown.

The fruits are about four months in ripening; but they appear and mature the whole year through. In point of fact, however, there are chief harvests, usually in early spring, but this is different for different countries.

The following extract from a comparatively recent consular report gives a clear idea of the modern method of cultivating the plant in some parts of South America. The extract was given in our former edition, but it is thought best to transcribe it here.

“The tree grows to the average height of thirteen feet, and from five to eight inches in diameter, is of spreading habit and healthy growth, and although requiring much more care and attention than the coffee-tree, yet its equally reliable crops require comparatively little labor in properly preparing for the market.

“... There are two varieties of the cocoa-tree cultivated in Venezuela, known as El Criollo and El Trinitario, respectively, the former of which, though not so prolific, nor as early fruiting as the latter, is yet superior to it in size, color, sweetness, and oleaginous properties of the fruit, and in the fact that it always finds ready sale, while the latter is often dull or neglected. The difference in price of the two varieties is also marked, the former being quoted at $28 to $30 per fanega (110 pounds), while the latter commands approximately half that price.

“While coffee can be successfully cultivated under a temperature of 60 degrees F., the cocoa-tree, for proper development and remunerative crops, requires a temperature of 80 degrees F.; hence the area of the cocoa belt is comparatively restricted, and the cocoa-planter presumably has not to fear the fierce competition that he has encountered in the cultivation of cotton and coffee. Besides the condition of temperature above stated, this crop needs a moist soil and humid atmosphere; and so the lands along the coast of the Caribbean sea, sloping from the mountain-tops to the shore, bedewed by the exhalations of the sea and irrigated by the numerous rivulets that course down the valleys, are found to be, in all respects, well adapted to the profitable cultivation of cocoa. And while the lands in the interior possessing facilities for irrigation may be said to be equally as good for the purpose, yet the absence of roads, and the consequently difficult transportation of produce on the backs of donkeys over rugged mountain paths, materially reduce the profits on the crop before it reaches the market.

“A cocoa plantation is set in quite the same manner as an apple-orchard, except that the young stalks may be transplanted from the nursery after two months’ growth. No preparation of the soil is deemed necessary, and no manures are applied. The young trees are planted about fifteen feet equidistant, which will accommodate two hundred trees to the acre. Between rows, and at like spaces, are planted rows of the Bucare, a tree of rapid growth, that serves to shade the soil as well as to shield the young trees from the torrid sun. Small permanent trenches must be maintained from tree to tree throughout the entire length of the rows, so that, at least once in the week, the stream, descending from the mountains, may be turned into these little channels and bear needful moisture to trees and soil. At the age of five years the plantation begins to bear fruit, and annually yields two crops, that ripening in June being termed the crop of San Juan, and that maturing at Christmas being known as the crop of La Navidad. The average age to which the trees attain, under proper care, may be estimated at forty years, during which period it will give fair to full crops of fruit; but of course it must be understood that, as in our fruit orchards, a new tree must be set from time to time to replace one that may be decayed or blighted. After careful inquiry it may be safely stated that the average crop of the cocoa plantation at ten years of age, and under a proper state of cultivation, will amount to five hundred or six hundred pounds per acre.”

The method of preparing the fruit for shipment is thus described in the “Encyclopædia Britannica”:--

“In gathering, the workman is careful to cut down only fully ripened pods, which he adroitly accomplishes with a long pole armed with two prongs, or a knife at its extremity. The pods are left in a heap on the ground for about twenty-four hours; they are then cut open and the seeds are taken out and carried in baskets to the place where they undergo the operation of sweating or curing. There the acid juice which accompanies the seeds is first drained off, after which they are placed in a sweating-box, in which they are enclosed and allowed to ferment for some time, great care being taken to keep the temperature from rising too high. The

fermenting process is, in some cases, affected by throwing the seeds into holes or trenches in the ground, and covering them with earth or clay. The seeds in this process, which is called “claying,” are occasionally stirred to keep the fermentation from proceeding too violently. The sweating is a process which requires the very greatest attention and experience, as on it, to a great extent, depends the flavor of the seeds and their fitness for preservation. The operation varies according to the state of the weather, but a period of about two days yields the best results. Thereafter the seeds are exposed to the sun for drying, and those of a fine quality should then assume a warm, reddish tint, which characterizes beans of a superior quality.”

Cocoa-beans are derived chiefly from the following sources, here arranged alphabetically. A recent author has classified them under two heads, unfermented and fermented; but this classification is very misleading, since it happens that from a few of the places mentioned variable proportions of both sorts are brought to market. Ariba (Ecuador), Bahia (Brazil), Caracas (Venezuela), Cayenne (French Guiana), Ceylon, Guatemala, Haiti, or Port au Prince, Java, Machala, or ordinary Guayaquil (Ecuador), Maracaiba (Colombia), Mararion (Brazil), St. Domingo, Surinam (Dutch Guiana), Trinidad (W. I.), from Africa, the Seychelles, Martinique, and Bourbon, variable amounts are beginning to appear as regular products. It is generally understood that some of the best sorts of South American cocoa are consumed at home and do not find their way, in definite quantities, or as a stated supply, to any foreign ports. Among these are Soconusco and Esmeraldas. At the last French exposition these and other very fine sorts from Venezuela and Ecuador were exhibited. New fields are being opened up in many directions to meet the increasing demand for the product.

III.

THE SEEDS OF THE CHOCOLATE-PLANT AS THEY APPEAR IN COMMERCE. THEIR MICROSCOPIC AND CHEMICAL CHARACTERS.

The seeds of the chocolate-plant are brought into the market in their crude state, as almond-shaped “beans,” which differ in color and somewhat in texture. It is not uncommon to find the external surface of the bean more or less covered with a thin irregular layer of attached earth, but this is generally pretty well cleared off during the transportation.

Upon the color of shell and kernel, the relative brittleness, the flavor, and the odor, depends the market value of the seeds.

The dried seeds have a papery, brittle shell, which is very smooth on the inside, but on the outside exhibits, under the microscope, a few short hairs and round excrescences. But these are mostly lost by the rough handling and by the attrition of the seeds with one another during transportation. The kernel consists of two large cotyledons or seed-leaves, reddish-gray or reddish-brown, with a shining, oily surface; the whole crushing rather easily into a loose mass of fragments. The kernel, when dry, has a minute, tough, almost stony radicle which separates easily from the cotyledons. Microscopic examination shows that the cells of the seed-leaves contain albumen, oily matters,--sometimes in a crystalline condition,--crystals of an entirely different shape, starch, coloring substances in special receptacles known as pigment-cells, and ducts with spiral markings. The starch grains do not have any very characteristic form or markings: they are generally spherical and simple. The only peculiarity worth mentioning, is the relative slowness with which they are acted on by hot water and by iodine. The coloring substances are mainly of a carmine or violet color, and are distinguished by the change of shade when an alkali is added, becoming thereby darker.

These are the only structural elements which a pure powder or paste of chocolate should show under the microscope. Any other substances must be recognized as accidental or intentional additions.

All seeds of whatever kind contain, as a part of their substance, the matter of which cell-walls are made; namely, cellulose. The percentage differs in different seeds, in those of the chocolate-plant being about three in the hundred. Cellulose has the same chemical composition as starch; but its physical properties are not the same as those of starch, among which may be mentioned its entire insolubility in boiling water.

Starch forms, on an average, eight to ten per cent of chocolate-seeds. It consists of minute spherical grains, not distinguishable from that found in many other kinds of seeds. Traces of gum and of other allied bodies are also present in the seeds.

Albuminoids, or substances resembling, in a general way, the albumin of egg, occur in chocolate-seeds as they do in other seeds, and in a somewhat higher amount than in certain other cases in which the seeds are used as food. The percentage ranges from about fifteen to twenty, depending on the variety. These albuminoids are compounds of nitrogen, and are extremely nutritious. In the seeds they occur in a readily assimilable form, fit for digestion. Their peculiar relations as flesh-formers are referred to in the

section treating of the physiology of chocolate-seeds.

Cacao-red occurs as a coloring matter in small amount. It is rendered dark by alkalies.

Theobromine, the active principle of the cocoa-bean, constitutes less than one per cent of the weight of the seeds, but it varies greatly in amount in different seeds, ranging from [illegible] of one per cent in some, to a trifle over one per cent in others.

The ash left on completely burning cocoa-beans is not far from four per cent. Its composition is substantially that of the ash of seeds of other plants.

Cocoa-butter, or oil, constitutes not far from fifty per cent of good cocoa-beans. The oil is remarkable for its freedom from rancidity and its very bland character. Its uses are innumerable.

The following averages of many analyses by a leading recent authority may be of interest:--

UNROASTED.

Moisture 7.11 Oil 51.78 Theobromine .35 Starch 5.78 Cellulose 3.1 Other carbohydrates, glucosides, etc. 10.05 Protein matters 15.61 Ash 3.60

ROASTED.

Moisture 6.51 Oil 49.24 Theobromine .43 Starch 10.43 Cellulose 3.1 Other carbohydrates, glucosides, etc. 7.78 Protein matters 18.33 Ash 3.92

IV.

MANUFACTURE OF CHOCOLATE AND BREAKFAST COCOA.

We have already called attention to the simple process by which the natives of Central America prepared a nutritious beverage from the seeds of the chocolate-plant. The essential features of this process, modified and greatly improved by modern science, are worthy of consideration at this time.

The selected cocoa-beans are first cleaned from the dust and attached particles which have come from various sources during the fermentation of the seeds. The machines for cleaning the beans are very ingenious and effective, removing from the seed-coat every trace of foreign matter.

The cleaned seeds are next roasted in the most careful manner, every precaution being taken to secure a uniform effect through the whole mass. During the roasting the seeds change color somewhat and become more or less modified in taste. In under-roasted seeds the flavor is not fully developed, while in over-roasted seeds the pleasant taste is likely to become greatly impaired, or it may even be wholly replaced by a bitter and harsh flavor. These relations of color and taste to the roasting of the seeds make this portion of the manufacture one of the most delicate processes from beginning to end.

By the roasting the shell becomes more readily detachable, and its complete removal is the next step. The crushing of the seeds into small fragments is easily accomplished; and this is followed by a thorough winnowing, by which the lighter shells are carried away by themselves, leaving the clean fragments of the roasted seeds ready for further manipulation.

Among the fragments can be detected minute and very tough bits of tissue. These bits are the hardened germs, or rather portions of the germs, and these are separated from the rest by an apparatus of much simplicity and efficiency.

The clean shells are usually placed at once in packages for transportation. They are extensively used for the domestic preparation of a wholesome and very low-priced drink. This beverage contains a fair proportion of the active principle of the chocolate-seeds themselves, and the flavor is suggestive of chocolate.

The cleaned fragments constitute the so-called “cocoa-nibs” of some foreign markets, and in this state they are used for the preparation of a simple decoction. But in this form they require to be boiled a good while for the development of flavor, and it is therefore better to have them treated beforehand in order to reduce the time of boiling; and this is all the more necessary, since during the long boiling a part of the more delicate aroma peculiar to chocolate-seeds is apt to be dissipated.

We are next to trace these fragments, through the chocolate-mill, and afterwards follow similar fragments through the cocoa-factory.

In the preparation of chocolate, the fragments are ground by a complicated mechanism until they attain the greatest degree of fineness, and constitute a perfectly homogeneous mass or paste. If the chocolate is to be a plain chocolate, it is to receive its delicate flavoring and then go directly into the moulds for shaping it. Every step of the process has to be watched with the most assiduous care. When the chocolate is formed and properly cooled, it is wrapped and packed for the market.

But if the chocolate is to be sweetened, a definite amount of the purest sugar, previously pulverized, is to be added, the whole ground and commingled, the proper flavoring of pure vanilla added, and the semi-solid mass formed in moulds as before. After being moulded it is sent to the packing-room and wrapped.

The variations in the process are innumerable, but all of them are comparatively unimportant when taken singly; the skill in the manufacture requires that each of these slight changes should be made at just the right time and in the right way. In the manufacture of Walter Baker and Co.'s chocolate, this skill has become developed to a very high degree during the hundred years of success. That the firm is ready to avail itself of every appliance known in modern manufacture, is seen by their adoption of the complicated machinery illustrated on page 29. This chocolate-machine has a capacity of five tons of pure chocolate daily. It is accessible to visitors, who may apply at the office in Dorchester for permission to see it in operation.

It is unnecessary to detail the steps of manufacture of many of the chocolate specialties of the firm.

We turn now to the consideration of breakfast cocoa.

The manufacture of breakfast cocoa is based upon two important factors: first, the removal of a definite portion of the cocoa-oil from the roasted seeds; and second, increasing the miscibility of the powdered seeds by securing the greatest practicable degree of fineness.

[Illustration: ONE OF THE CHOCOLATE-MACHINES AT THE MANUFACTORY OF WALTER BAKER & CO.

CAPACITY, FIVE TONS OF CHOCOLATE DAILY.]

While the oil of the chocolate-seed is perfectly wholesome, there are some persons who find in the percentage natural to the seeds a too large amount for easy digestion. The removal of a part of this, which might with propriety be called an excess of the oil, was practised even in very early days, as is seen in the cut herewith given, taken from an old work on the subject. The present method of extracting the oil is not essentially different, save in a few particulars, from that here figured, and therefore need not be described in detail.

[Illustration]

The method of manufacture is substantially as follows: the ground fragments of roasted seeds are subjected to pressure, and with the result of withdrawing just as much oil as the manufacturers desire to abstract. The pressed mass is, in the most successful process, treated mechanically in such a manner as to divide and subdivide the minute particles until they are capable of passing through a sieve having several thousand meshes to the square inch. But such pulverization as this would, under ordinary circumstances, reduce the mass to a dull and unattractive powder. In the process devised by the firm of Walter Baker and Co., this high degree of fineness is secured without any loss of brilliancy in the powder,--the color being of the bright-red which is not only attractive in appearance, but when conjoined with the natural chocolate odor and flavor is characteristic of absolutely pure cocoa of the highest grade.

It is instructive to compare such cocoa with the cocoas prepared by what is known in chemical technology as the chemical process. The latter are prepared by treatment with alkaline matters which act on the coloring substances in the seeds, increasing the apparent effect of hot water when the latter is added. In chemically prepared cocoas, the exquisite natural odor and flavor of pure cocoa-seeds have been diminished or wholly lost by the severe treatment to which the materials have been subjected. In some cases the loss of the natural flavor is sought to be partially supplied by the use of fragrant gums, wholly foreign to the natural product.

The detection of these admixtures is generally easy. Comparison with the well-known pure breakfast cocoa of Walter Baker and Co. will reveal at once the vast superiority of a product which has not been treated by chemicals, but which contains only the finest

possible powder of the best chocolate-seeds freed from the excess of oil. The exquisite flavor and odor of the pure product are due wholly to the seeds themselves, since absolutely no foreign matter is added from first to last. Walter Baker and Co.'s breakfast cocoa can be used by students of the microscope and of chemistry as a perfect type of the highest order of excellence in manufacture. The enormous increase in consumption of Baker's cocoa and chocolate indicates that our discriminating public appreciate a thoroughly good article when they see it.

V.

SOME PHYSIOLOGICAL ASPECTS OF CHOCOLATE-SEEDS.--VALUE OF CHOCOLATE AS AN ARTICLE OF FOOD.

The seeds of plants contain a germ, or embryo, together with a certain amount of food. As soon as the germ sprouts, the food, or a good part of it, is consumed by the seedling, being used by it in the formation of new parts, such as roots and leaves by which the materials for more food can be obtained from the soil and air. Now it happens that the food of plants is pretty much the same as the food of animals, although there is this marked difference in the manner of procuring it: plants can construct their own food from inorganic or mineral matters taken from the earth and atmosphere, while animals, even those which are most like plants, must have their supply of food from organic nature.

Since, then, plants prepare the food which animals are to use (of course flesh-eating animals use their plants, so to speak, at second-hand), it comes to pass very naturally that the food in a good many seeds has been recognized from early times as very useful food for man. Thus the cereals--wheat, maize, oats, barley, and rice--are the seeds of grasses; and there are many other seeds, such as beans, peas, buckwheat, and so on, which have been appropriated as food by man from remote antiquity. But the seeds of some plants are unfit for human food, owing to disagreeable properties which they possess; while there are a few which stand on the very edge of the limit of foods, and have been used in time of scarcity.

The seeds of at least two plants are used as important adjuncts to our list of foods, and can be enumerated among foods without any impropriety. These are coffee and cocoa. They contain nutritive properties,--the latter in very much higher degree than the former,--and they possess also peculiar constituents which entitle them to rank as luxuries. These peculiar constituents are (1) flavoring matters, and (2) an active principle. But, either from its constitution or from its association in the seed, the active principle of coffee, although it has nearly or quite the same ultimate composition as the active principle of cocoa, is unlike it in its effects. The active principle of cocoa is substantially free, as used in its preparations, from any undesirable effects on the nervous system. This active principle of cocoa is _Theobromine_.

The essentials of a perfect food are (1) a certain amount of carbohydrates, (2) of albuminoids, and (3) certain mineral matters, these latter being substantially the same in all seeds used as food. In cocoa these three groups are combined in proper proportion to constitute a complete food, but there is superadded the active principle, _Theobromine_, which places it at once in the class of luxuries as well as of necessary foods.

When cocoa-seeds are prepared properly for food, without doing violence to the chemical relations of the different components, a comforting nutritive article of the highest value is obtained. This ideal method of preparation is not a chemical torturing by the addition of foreign ingredients, as in the alkali process, but it consists in the complete unlocking, by perfectly natural, mechanical means, of all the virtues of the seeds. We do not try to render the albuminoids of wheat and other grains soluble by means of ammonia, soda, or potash, nor do we think it desirable to increase the solubility of the albuminoids of egg and meat by adding caustic or carbonated alkalies to them before they are used. And yet chemical processes analogous to these have been devised and are sometimes used with regard to cocoa. In most cases these added substances are detected in the increased amount of mineral matters found in the ash after burning the preparation. The amount of ash in pure cocoa is about four per cent. Any appreciable amount above this may be attributed to the admixture of mineral matters used in the preparation.

The oil in pure chocolate-seeds is about fifty per cent of the whole weight. Although the oil is exceedingly bland and free from rancidity, it has been found expedient in some cases to withdraw a part of this oil, leaving a smaller amount in the product. This is the method pursued in the manufacture of the powdered cocoas. With this reduction in the quantity of oil, the resultant beverage is less likely to disagree with delicate digestion.

It is in all cases of the first importance to obtain only pure cocoa of the highest quality, free from any admixture of foreign matter, such as the alkalies or their carbonates; and further, the product ought to be of the greatest degree of fineness. With regard to the flavors added to chocolate, it is perhaps needless to say that they should be of the utmost degree of purity. This is especially true of

vanilla, which owing to its high cost is frequently replaced by artificial flavors. There is, in one respect, a notable difference between sweet chocolate and cocoa: the former may be flavored, the latter should never be. A pure cocoa must be absolutely dependent on its own delicious, natural odor and flavor. No addition of any substance of any kind is admissible.

SUGGESTIONS RELATIVE TO THE COOKING OF CHOCOLATE AND COCOA.

BY MRS. ELLEN H. RICHARDS,

Of the Massachusetts Institute of Technology.

The flavor of the cocoa-bean seems to be almost universally liked, and the use of the various preparations made from it is constantly increasing. From the sweet chocolate with which the traveller now provides himself in all journeys in which the supply of food is doubtful either in quantity or quality, to delicate coloring and flavoring of cakes and ices, nearly all kinds of culinary preparations have benefited by the abundance of this favorite substance.

In these forms, chocolate is used in a semi-raw state, the bean having been simply roasted at a gentle heat, ground, and mixed with sugar, which holds the fat. By varying the quantity of the chocolate to be mixed with the ingredients of the cake or ice, an unlimited variety of flavors can be obtained.

In preparing it as a beverage for the table a mistake has been frequently made in considering chocolate merely as a flavor, an adjunct to the rest of the meal, instead of giving it its due prominence as a real food, containing all of the necessary nutritive principles. A cup of chocolate made with sugar and milk is in itself a fair breakfast.

There is much to be said in favor of preparations of the whole bean which secure all of the valuable nutrition contained in this “food for the gods,” and rightly understood, it is possible to make them more important articles of diet than they now are. But since the large percentage of fat seems to require correspondingly large quantities of sugar to render the beverage palatable, and this very rich, sweet drink soon cloys if made strong enough to be nutritious, it is, fortunately, possible to extract the larger part of the fat without injury to the flavor so characteristic of chocolate. In this form, called cocoa, less sugar and more milk are needed, and the resulting beverage suits even delicate stomachs, and is yet of high food value.

It is the object of all cooking to render raw material more palatable and more nutritious, and therefore more digestible. The cooking of cocoa and chocolate is no exception to this rule. Certain extractive principles are soluble only in water which has reached the boiling-point; and the starch, which the seed contains, is swollen only at this temperature.

Chocolate or cocoa is not properly cooked by having boiling water poured over it. It is true that as the whole powder is in suspension and is swallowed, its food material can be assimilated as it is when the prepared chocolate is eaten raw; but in order to bring out the full, fine flavor and to secure the most complete digestibility, the preparation, whatever it be, should be subjected to the boiling-point for a few minutes. In this all connoisseurs are agreed.

RECEIPTS.

BY MISS PARLOA.

PLAIN CHOCOLATE.

For six people, use one quart of milk, two ounces of W. Baker & Co.’s No. 1 chocolate, one tablespoonful of corn-starch, three tablespoonfuls of sugar, and two tablespoonfuls of hot water.

Mix the corn-starch with one gill of the milk. Put the remainder of the milk on to heat in the double-boiler. When the milk comes to the boiling-point stir in the corn-starch, and cook for ten minutes. Have the chocolate cut in fine bits and put it in a small iron or granite-ware pan; add the sugar and water, and place the pan over a hot fire. Stir constantly until the mixture is smooth and glossy. Add this to the hot milk and beat the mixture with a whisk until it is frothy. Or the chocolate may be poured back and forth from the boiler to a pitcher, holding high the vessel from which you pour. This will give a thick froth. Serve at once.

If you prefer not to have the chocolate thick, omit the corn-starch.

CHOCOLATE MADE WITH CONDENSED MILK.

Follow the rule for plain chocolate, substituting water for the milk, and adding three tablespoonfuls of condensed milk when the chocolate is added.

CHOCOLATE; VIENNA STYLE.

Use four ounces of vanilla chocolate, one quart of milk, three tablespoonfuls of hot water, and one tablespoonful of sugar.

Cut the chocolate in fine bits. Put the milk on the stove in the double-boiler, and when it has been heated to the boiling-point, put the chocolate, sugar, and water in a small iron or granite-ware pan and stir over a hot fire until smooth and glossy. Stir this mixture into the hot milk, and beat well with a whisk. Serve at once, putting a tablespoonful of whipped cream in each cup and then filling up with the chocolate.

The plain chocolate may be used instead of the vanilla, but in that case use a teaspoonful of vanilla extract and three generous tablespoonfuls of sugar instead of one.

BREAKFAST COCOA.

Breakfast cocoa is powdered so fine that it can be dissolved by pouring boiling water on it. For this reason it is often prepared at the table. A small teaspoonful of the powder is put in the cup with a teaspoonful of sugar; on this is poured two-thirds of a cupful of boiling water, and milk or cream is added to suit the individual taste. This is very convenient; but cocoa is not nearly so good when prepared in this manner as when it is boiled.

For six cupfuls of cocoa use two tablespoonfuls of the powder, two tablespoonfuls of sugar, half a pint of boiling water, and a pint and a half of milk. Put the milk on the stove in the double-boiler. Put the cocoa and sugar in a saucepan and gradually pour the hot water upon them, stirring all the time. Place the saucepan on the fire and stir until the contents boil. Let this mixture boil for five minutes; then add the boiling milk, and serve.

A gill of cream is a great addition to this cocoa.

CHOCOLATE CAKE.

For two sheets of cake use three ounces of W. Baker & Co.’s No. 1 chocolate, three eggs, one cupful and three-fourths of sifted pastry flour, one cupful and three-fourths of sugar, half a cupful of butter, half a cupful of milk, half a teaspoonful of vanilla extract, one teaspoonful and a half of baking powder.

Grate the chocolate. Beat the butter to a cream and gradually beat in the sugar. Beat in the milk and vanilla, then the eggs (already well beaten), next the chocolate, and finally the flour, in which the baking powder should be mixed. Pour into two well-buttered shallow cake-pans. Bake for twenty-five minutes in a moderate oven. Frost or not, as you like.

VANILLA FROSTING.

Break the white of one large egg into a bowl, and gradually beat into it one cupful of confectioner’s sugar. Beat for three minutes, add half a teaspoonful of vanilla extract, and spread thinly on the cakes.

CHOCOLATE ICING.

Make a vanilla icing and add one tablespoonful of cold water to it. Scrape fine one ounce of No. 1 chocolate and put it in a small iron or granite-ware saucepan with two tablespoonfuls of confectioner’s sugar and one tablespoonful of hot water. Stir over a hot fire until smooth and glossy, then add another tablespoonful of hot water. Stir the dissolved chocolate into the vanilla icing.

CHOCOLATE ICE-CREAM.

For about two quarts and a half of cream use a pint and a half of milk, a quart of thin cream, two cupfuls of sugar, two ounces of No. 1 chocolate, two eggs, and two heaping tablespoonfuls of flour.

Put the milk on to boil in the double-boiler. Put the flour and one cupful of the sugar in a bowl; add the eggs, and beat the mixture until light. Stir this into the boiling milk and cook for twenty minutes, stirring often.

Scrape the chocolate and put it in a small saucepan. Add four tablespoonfuls of sugar (which should be taken from the second cupful) and two tablespoonfuls of hot water. Stir over a hot fire until smooth and glossy. Add this to the cooking mixture.

When the preparation has cooked for twenty minutes take it from the fire and add the remainder of the sugar and the cream, which should be gradually beaten into the hot mixture. Set away to cool, and when cold, freeze.

CHOCOLATE PUDDING.

For a small pudding use one pint of milk, two tablespoonfuls and a half of corn-starch, one ounce of chocolate, two eggs, five tablespoonfuls of powdered sugar, one-fourth of a teaspoonful of salt, and half a teaspoonful of vanilla extract.

Mix the corn-starch with one gill of the milk. Put the remainder of the milk on to boil in the double-boiler. Scrape the chocolate. When the milk boils, add the corn-starch, salt, and chocolate, and cook for ten minutes. Beat the yolks of the eggs with three tablespoonfuls of the sugar. Pour the hot mixture on this and beat well. Turn into a pudding-dish that will hold about a quart, and bake for twenty minutes in a moderate oven.

Beat the whites of the eggs to a stiff, dry froth, and gradually beat in the remaining two tablespoonfuls of sugar and the vanilla. Spread this on the pudding and return to the oven. Cook for fifteen minutes longer, but with the oven-door open. Serve either cold or hot.

BAVARIAN CHOCOLATE CREAM.

For one large mould of cream, use half a package of gelatine, one gill of milk, two quarts of whipped cream, one gill of sugar, and one ounce of chocolate.

Soak the gelatine in the cold water for two hours. Whip and drain the cream, scrape the chocolate, and put the milk on to boil. Put the chocolate, two tablespoonfuls of sugar, and one of hot water, in a small saucepan, and stir on a hot fire until smooth and glossy. Stir this into the hot milk. Now add the soaked gelatine and the remainder of the sugar. Strain this mixture into a basin that will hold two quarts or more. Place the basin in a pan of ice-water and stir until the mixture is cold, when it will begin to thicken. Instantly begin to stir in the whipped cream, adding half the amount at first. When all the cream has been added, dip the mould in cold water and then turn the cream into it. Place in the ice-chest for an hour or more.

At serving-time dip the mould in tepid water. See that the cream will come from the sides of the mould, and turn out on a flat dish. Serve with whipped cream.

==========

How and what to grow in a kitchen garden of one acre

E. D. Darlington

Project Gutenberg Release: September 25, 2025 · eBook #76930

HOW AND WHAT TO GROW IN A KITCHEN GARDEN

OF ONE ACRE.

DARLINGTON AND MOLL.

THE

Poultry Yard.

HOW TO FURNISH AND MANAGE IT.

BY W. ATLEE BURPEE.

Full descriptions and large illustrations given of the leading varieties of Land and Water Fowls. It also contains chapters on POULTRY HOUSES, SELECTION AND MATING OF STOCK, WHAT AND HOW TO FEED, GENERAL MANAGEMENT, DRESSING AND SHIPPING POULTRY, EGGS AND CHICKENS, DIRECTIONS FOR CAPONIZING, DISEASES, HOW TO RAISE GOOD TURKEYS, ETC., ETC. Fully Illustrated.

THE NEW EDITION for 1888 contains, besides the above, an illustrated chapter on the training and care of SCOTCH COLLY or SHEPHERD DOGS, also new improved plans of Poultry Houses, with illustration.

Price, 50 CTS. in paper; 75 CTS. bound in cloth. Sent, postpaid, by mail, upon receipt of price by the Publishers,

W. ATLEE BURPEE & CO., PHILADELPHIA, PA., _and at 133 Cannon St., London, E. C., England_.

☛ BURPEE'S ILLUSTRATED CATALOGUE of THOROUGHBRED LIVE STOCK and FANCY POULTRY sent free, on application, to all interested.

HOW AND WHAT TO GROW

IN A

KITCHEN GARDEN

OF ONE ACRE.

BY E. D. DARLINGTON AND L. M. MOLL.

EDITED BY W. ATLEE BURPEE.

[Illustration]

1888. PUBLISHED BY W. ATLEE BURPEE & CO., NOS. 475 AND 477 NORTH FIFTH STREET, NOS. 476 AND 478 YORK AVENUE, PHILADELPHIA.

COPYRIGHTED, 1888, BY W. ATLEE BURPEE & CO., PHILADELPHIA, PA.

EDITOR'S PREFACE.

In Burpee's Farm Annual for 1887 we offered cash prizes for the two best essays, to be sent us by October, 1887, upon the subject, "HOW AND WHAT TO GROW IN A KITCHEN GARDEN OF ONE ACRE." In its original form E. D. DARLINGTON'S essay covered more fully than any other the operations and best methods to pursue in the management of the garden, and was awarded the first

prize. Being desirous, however, of making this work not only practical but thoroughly complete in all departments, and from personal acquaintance with Mr. Darlington and his gardening operations, together with the fact that for some years he had tested numerous varieties of vegetables for us, we arranged with him to entirely revise and enlarge his essay. In compliance with our request he has entered more into detail in the directions for culture, and has added impartial descriptions of the varieties that he has found best adapted both to the Kitchen Garden and the table. To make the treatise more complete, he prepared a diagram of his own kitchen garden, which is one acre in size, as laid out for a year's work. Some varieties grown are not marked in the diagram, as they are worked in as parts of other rows, but this is all fully explained in the body of his treatise.

To add to the value of the book as a plain and practical guide for the novice in gardening, we have had illustrations engraved showing the two plans of hotbeds, the methods of storing roots for winter use, etc. We have also inserted engravings, mostly drawn from nature, of the leading varieties of vegetables described in the text, that the gardener may have an accurate idea of the form of the different varieties and may be able to tell whether his products are of the right type.

We take pleasure, also, in publishing the essay of Miss L. M. MOLL, of Illinois, which was awarded the second prize. We are glad to note that she has been explicit in describing the culture of some of the less generally grown varieties of salads and herbs which are valuable adjuncts to the table, and upon which Mr. Darlington has failed to treat. Some of the methods described in this essay are, however, unnecessarily laborious. For instance, the wide bed of perennials, as described, would require considerable hand labor to keep the soil loose and free from weeds; while, if planted in long rows, horse cultivation would lessen this tedious work and would also loosen the ground to a greater depth. The varieties recommended by Miss Moll, while generally good, have in some cases been surpassed by improved varieties of more recent introduction.

As presented in the following pages, the two essays will, we believe, make this book, for general use, the most complete and practical treatise on gardening published. Such has been our earnest endeavor, and we are confident that it will be recognized as a thoroughly trustworthy guide. With careful study of its teachings, the novice should be able to plant and successfully manage a Kitchen Garden, be it one acre, more or less, while we trust that experienced gardeners will find much to commend and will be able to gain some new ideas.

W. ATLEE BURPEE.

PHILADELPHIA, December 16th, 1887.

HOW AND WHAT TO GROW

IN A KITCHEN GARDEN

OF ONE ACRE.

BY E. D. DARLINGTON.

In order to treat this subject in detail, I shall first write on what the kitchen garden should be, where it should be, and how to keep it in the best order to produce the desired results, then take up "What to grow" and "How to grow it."

SITUATION OF THE GARDEN.

The garden should be situated conveniently near the farm buildings, as it should be visited frequently; a variety of tools are needed in its care, and each should be put away as soon as done with, that it may be preserved in the best order for use. It is often necessary to carry water to help along young transplanted stock that has been overtaken by a dry spell. Where the distance has to be traversed so frequently, it naturally follows that the shorter it is the greater will be the saving in time and the less likely is the garden to be neglected.

The garden should be as nearly level as possible, or, if sloping, not so much so as to be in danger of being washed by heavy rains. If sloping, the slope should lie to the south, or as nearly south as possible. A plantation or hedge of evergreens on the north side of the garden will be found a wonderful aid to the earliness of the garden truck and to the hardiness of the small fruit plants and roots which remain in the ground all winter; if a woods or high hill be directly on the north and northwest of your garden, it will answer nearly as well as the hedge of evergreens. The garden should be so situated as to have good surface drainage; without this or expensive underdraining, it will hardly be possible to raise early or fine vegetables at any profit. These I consider the most essential

points in selecting the plot for the garden; of course, a good, rich soil is to be desired, but the gardener can, by the liberal use of manure and thorough cultivation, remedy a deficiency of this kind in a couple of years, while he cannot make a favorable location for early vegetables on a north slope if he should try a lifetime. By a careful study of the varieties in cultivation, and by trials of their merits in your garden and _on your table_, experience will be gained which will enable you to grow as fine vegetables and fruits on heavy soil as on light, sandy loam, and _vice versa_.

THE SOIL OF THE GARDEN.

Ground that has been worked in some cultivated farm crop, such as corn or potatoes, is more desirable for starting a garden than fresh sod land, as it is more easily brought into fine condition in the early spring; while grass is one of the hardest weeds to exterminate, especially among small hoed crops, such as strawberries, onions, beets, etc. Sod land is also often full of grubs, which work havoc among the strawberry plants and young melon and squash vines. In either new ground or in the old established garden, it will be of great advantage to put the long, coarse manure on the ground in the fall, and plow it well under as soon as the ground can be cleared of the summer crops. The soil should be left just as it is plowed, without harrowing, leaving the lumps and ridges to the action of the frost. This will be found of especial benefit to heavy soils that are late in drying in the spring; it also adds a great deal to the appearance and cleanliness of the garden, as the weeds, old stalks, etc., are all cut off and burnt before plowing, instead of being left to scatter their seeds with every winter wind.

The gases arising from the decaying of the coarse manure in the soil tend to lighten it, instead of being wasted in the air, as is the case when the manure is in heaps or in the barnyard. By plowing-time in the spring the manure will have assimilated with the soil and will be thoroughly worked through the cultivated surface, thus affording food for the crops in all stages. If such manure is applied in the spring, it will make dry or thin soil still drier, and unless plowed well under, where it would take the roots a long time to reach it, will burn the young plants up if the season should happen to be a dry one. The great value of compost in starting young plants is that it affords rich food in proper form for the tender young rootlets, enabling the young plants to make a quick, tender growth, which is very essential if vegetables of fine quality are desired. By fall manuring and plowing the whole garden is composted, while the action of the frost on the lumps and ridges pulverizes them, leaving the soil in a fine, friable condition.

LAYING OUT THE GARDEN.

It is most convenient to have the garden as nearly square as possible, which in our garden of one acre will be 208 x 208 feet. This makes the length of the rows a very good measure of the quantity to be grown, and affords as many rows to the ground as can be profitably worked, for it is desirable that the rows should be as nearly east and west as possible, and they should be the long way of the plot (if not a square), as it will result in great saving of time in planting and cultivating. Moving the line and drawing the cultivators out of one row and turning into the next, takes nearly as much time as the working of the short row.

In plowing, a good, wide headland should be left at each end of the garden; it should be wide enough to allow the horse and cultivator to come clear out from between the rows and to turn into the next row, without damaging the plants at the ends of the rows by trampling and dragging the cultivator over them.

In winter, while there is plenty of time before the spring opens, the summer campaign should be planned--what vegetables are to be raised and what quantity of each will be needed, in what part of the garden it will be best to plant each variety so that the pollen from different members of the same family, such as cucumbers and cantaloupes, will not mix and spoil each other’s fine flavor. If the soil is of different quality in different parts of the garden, it should be planned so that the heavy and the lighter portions shall be occupied by such crops as will succeed best in the respective soils.

Ease of cultivation and the rotation or succession of crops should also be considered. The small-growing plants which require hand hoeing should be together, and likewise those which are to be worked with the horse cultivator. Where the ground is to bear two crops--one planted after the other has matured and been taken off--it will be of advantage to have such crops together, thus making larger plots for the replowing and a consequent saving of time and work.

Beside these conditions in laying out a new garden, when it comes to the second or succeeding seasons, the crop or crops raised in the plot the year before must be taken into account. The situation of the crop of each particular vegetable should be moved to another part, as each draws certain proportions of the food elements from the soil, and those of a different character should occupy the ground in rotation, that the soil may be kept in the richest state. Thus the quality or size of the crop will not be lessened by being planted in a situation that it has depleted, to some extent, of its own particular food the year before. Reference should also be had

to the kind of food which the plant requires, as in the case of strawberries and potatoes, which should not succeed each other without special manures, as they both exhaust, to a great extent, the potash in the soil, so that the soil, having borne a heavy crop of one, would of necessity make but a poor return of the other if planted in direct succession. If this cannot be overcome by a change of location, the gardener will know that the proper food elements have been depleted by the previous crop, and must try to supply them with special manure or commercial fertilizers.

It is of great importance to rapid work and good gardening that all this should be arranged and settled in the gardener's mind, or better, plotted out on paper, before the first plowing is done in the spring. The plan being kept would be valuable in laying out the garden the succeeding year, as it would show just where each vegetable had been grown and where the different kinds of manure had been applied. If, in addition, the success of the various crops and notes of their growth were marked upon it, it would form a most valuable text-book for the study of improved gardening, each garden being an experimental station and each gardener a student in pursuit of knowledge and advancement in his work, feeding at the same time both physical and intellectual needs.

DIAGRAM OF THE GARDEN.

The accompanying plan may be of use to the novice in gardening on the scale suggested by our subject, as it is planned to admit of a proportionate quantity of such vegetables and fruits as are grown in the ordinary garden, while directions for planting and cultivating the various vegetables will be found in the special descriptions of the several varieties. (See p. 16.)

PROCURING THE SEEDS AND PLANTS.

[Illustration:

KEY TO DIAGRAM.

ROW NO. 1. 25 grape vines, planted about 7½ feet apart. The first three years these are trained to plain stakes or bean poles, the space in the rows between the vines being planted with strawberries, peas, beans or some other low-growing crop, to occupy the ground and insure good cultivation. When the vines have made strong canes and have reached the tops of the poles, a post is set at each vine and a trellis made, as described in the chapter on grapes. This row is six feet distant from the north boundary line of the garden.

ROWS NO. 2. These rows are twelve feet distant from each other and from the row of grapes, and are planted with blackberry vines, at a distance of three feet in the rows. Though this may seem like a good deal of "elbow room," it is as close as they can be planted to keep them in good order; if planted closer they will form an impenetrable jungle by the end of the second season.

ROWS NO. 3. These two rows are planted with red and black raspberries, the rows also twelve feet apart, but the plants set 2½ feet apart in the rows.

ROW NO. 4. This is planted with rhubarb, sage and thyme, currants and gooseberries, and is twelve feet distant from the rows on either side.

ROW NO. 5. Is twelve feet from row No. 4, and is planted with asparagus, as described in the special chapter on that vegetable.

ROWS NO. 6. These two rows are to be planted with spring-set strawberries for the next year's crop, and are four feet distant from the asparagus and from each other. The strawberries are intended to be grown on the matted row plan, and to be cultivated with the horse cultivator; if they are to be grown in stools, another row can be planted between them, and the whole worked with the wheel or hand hoes.

ROW NO. 7. This row is for watermelons or cantaloupes, and the line of hills is six feet distant from the row on either side. The space in the row between the hills can be planted with egg plants, cabbage, lettuce or such other plants as may be desired.

ROW NO. 8. This row is a space four feet wide, with room for the cultivator on either side; this is raked fine and planted in four rows one foot apart, the first row containing beets and carrots; the second, onions; the third, lettuce, radishes, etc.; the fourth, with a dozen plants of parsley, and the balance of the row in endive and parsnips. When the two middle rows have been cut out, the cultivator can be used to work the beets, parsnips, etc., in the outside rows.

ROW NO. 9. This row is three feet distant from the parsnips, and is planted with early cauliflower and early cabbage, with two plants of lettuce between each of the other plants, which are set 1½ feet apart.

ROWS NO. 10. These are four rows of peas, different plantings, two kinds, early and medium, in each row, in equal quantities, rows three feet apart. These are to be pulled out as soon as the crop is gathered, and two rows of celery planted six feet apart.

ROWS NO. 11. Here are four rows of early sweet corn, in four plantings of successive kinds, to be cleared off and followed by turnips, drilled in rows one foot apart, and worked with the wheel hoe; or the seed may be broad-casted after a thorough cultivating, when the ears of corn are well set, without clearing the ground. This is not nearly so satisfactory a plan as to wait until the ground can be cleared and drilled. The rows of corn should be four feet apart.

ROWS NO. 12. Two rows, 4½ feet apart, of Lima beans, with the poles about 2½ feet apart in the row.

ROW NO. 13. This row should have six feet clear on each side for the vines to run, and is to be planted with cucumbers and squashes. The space between the hills can be occupied with pepper plants or sweet corn.

ROWS NO. 14. Two rows of tomatoes, four feet apart.

ROWS NO. 15. Four rows of late sweet corn, four feet apart.

ROWS NO. 16. Two rows of sweet potatoes, five feet apart and five feet from the corn and pole beans on either side.

ROW NO. 17. One row of pole snap beans. About three kinds should be planted, that they may be had in succession.

ROWS NO. 18. Five rows early potatoes, three feet apart, plowed in when the ground is plowed in the spring. When cultivated for the last time, plant a row of late cabbage between each row of potatoes; when the latter are ripe, dig with a fork, clear the ground of vines and cultivate the cabbage thoroughly.

ROWS NO. 19. Sweet corn planted between the rows of berry bushes; a large late variety will be the best for this purpose.

ROWS NO. 20. Two rows of fruiting strawberries, to be plowed under and be replaced by peas sown in August. This, of course, applies only to a garden of at least a year's standing; and the fruiting plants of strawberries will come in a fresh place each year. The rows No. 6 being the bearing plants next season.]

Having the plan of work all settled, the next thing is to know what is to be grown, the varieties of each that are best adapted to the situation and soil of the garden, and where they can be procured of the best quality. Under this head come the seeds needed for the vegetables and the roots, tips and runners for the plantings of small fruits. This should be done as soon as convenient, as I have found by experience it is a great saving to have the entire supply of seeds on hand a week or two before it is possible to begin planting. This is an important item, as I have sometimes lost my crop from planting inferior seed purchased at the last moment from the commissioned seeds that are sold in the country stores. It does not pay to economize or try to garden with poor seeds; it is a waste of time and labor in planting, and a waste of ground and manure, as the inferior vegetables raised will hardly cover the original cost of the seed. The gardener who sells his products, unless his crops are of the best, will soon find his trade falling off, and will be compelled to seek new customers each market day. Personally, I have found it more satisfactory and productive of better results to buy each season almost all the seeds needed from some reliable seedsman, rather than to depend on those of my own saving. For instance, such as peas, sweet corn and other vegetables, where the earlier the crop is ready to market the greater the profit; these mature much earlier if the seed is procured from reliable seedsmen who have their supplies grown in the North. Such northern grown seeds retain their instinct to hurry up and mature in a short season, while in one's own saving they begin even in the first year to grow more leisurely and to accommodate themselves to the longer season. In the case of peas, those grown in Northern New York and Canada, such as are sold by all our leading seedsmen, will mature from one to two weeks earlier than those saved in our own neighborhood. The northern peas are also generally free from the weevil or striped bug, which bores the large round hole in all the home-saved peas and destroys their germinating power. So it is with almost every known variety of vegetable; each has some special locality in which it reaches a higher degree of perfection than in others less favorably situated. While, of course, these facts are of interest to the gardener, they are only learned after years of experience, and it is the seedsman's business to know the peculiarities of the different varieties, and to raise or procure his stock from the best strains grown in the most favorable localities. It is for the gardener to purchase from a seedsman whom he knows to be thoroughly reliable, and whose interest it will be to serve him with prompt shipments and carefully-selected strains of the vegetables desired. All this is equally true of the nursery-man or small-fruit grower from whom the supply of roots and plants is to be purchased. On no part of the farm is "_Pedigree Stock_" of more importance than in the kitchen garden. I will speak further on of the saving of seeds, and refer now only to those which it is necessary to buy. First, it is often a saving of several days to have the seed on hand, as it is

sometimes impossible to foretell just when you will need the seed to plant a certain plot, how soon the ground will be fit to work, or how soon will come the opportunity, in the press of other work; if you have the seed at hand that part is always ready, and this is quite an item where the garden frequently has to be attended to in the intervals of farm work. Next, it is a cash saving to order all your seeds at one time. If, as is most frequently the case, you have to send to some large city for your supply, by procuring all that you need at one time, you have but one freight or express charge to pay. In making up your order, stick to the old varieties that you know suit your soil and your market; all the more if your market is your own table, for the greatest pleasure in gardening is in testing the merits of your fruits and vegetables with the appetite engendered by their culture. Also take into consideration the preferences of the household department as to the cooking merits of the different varieties. Do not experiment with your main crop of any vegetable, but do not neglect to try such new varieties as seem to possess merit, for the varieties are being continually improved by good culture and selection, as well as by hybridization or cross-breeding. To have a fine garden, the gardener must know the merits of all new and old varieties, and be as progressive as is the successful man in any other line of business. I know of nothing so interesting as watching the growth and development of some new and improved variety that has been recommended to the gardening public in the most glowing terms, and often in glowing colors on a beautiful colored plate. Although I have been “taken in” fully as often as the average gardener of my experience, I have been many times repaid all trouble and outlay by the numerous successes that I have met with and the great improvement in some of the varieties grown. Sometimes I have made quite a nice little sum out of these novelties, when I have been able to sell the selected seed of the new variety to some other seedsman or to my neighbors. In these new varieties, more than in any others, do you need to order early, or, instead of the seed that you desire and which is to make reputation and money for you, “being something superior to anything ever grown before,” you may get one of those provoking little slips stating that the seedsman “regrets to inform you that, owing to the great demand, the supply is exhausted for this season, and hopes that the substituted kind will do as well.”

HOTBEDS AND COLD FRAMES.

With a garden of this size I would have hotbeds, cold frames and rich seed beds of fine light soil; these I would not have in the garden itself unless that be the most convenient place. Where there is time to attend to them, they will be a measure of economy, it being much cheaper to raise than to buy the plants, if you use more than a few dozens, while, if you have the time and room, quite a business can be done by supplying your neighbors who do not garden on such an extensive scale. It is best to locate the frames on the sunny side of a barnyard wall, or against a building that will shield them from the north wind and make a warm nook for them on sunshiny days. They should be situated conveniently near both to the manure pile and to a good supply of water, where they will constantly be under the eye in passing to and from the farm work and will not suffer neglect from being forgotten or overlooked. It is quite important that there should be good drainage from these beds, as they are most needed at a rainy time of the year; dampness is not only injurious to the young plants, but it also takes up a great deal of the heat which should go toward forwarding the growth of the young plants. The sashes can be bought, ready painted and glazed, at the planing mills in most cities, and this is much the cheapest way to procure them, as they can often be bought for what the bare sash would cost in a small order at a country shop. They come 3¼ feet wide by 6 feet in length, and are 1½ to 2 inches in thickness, and if stored in the dry when not in use, and are treated to an occasional coat of paint, will last a lifetime.

Three or four sash would be amply sufficient for a garden of an acre if used in succession, sowing one lot of seed as the preceding planting is set out in the garden; though, of course, more sash can be handled without any great increase of labor, and the season much advanced by growing radishes, lettuce, beets, etc., to maturity under the glass.

[Illustration: Illustration showing the manner of making the hotbed when sunk below the surface of the ground.]

In making the hotbed, dig a trench a few inches short of six feet in width, or as wide as the sashes will cover, about two feet in depth and as long as the combined width of the number of sashes which you wish to use. This is then to be boarded up with rough boards, but they should be neatly joined and plastering laths or building paper tacked over the cracks, so as not to waste the heat. The back or north side of this frame should be 6 or 8 inches higher than the front, so that the rain may run off the sashes. The sashes held at an angle in this manner will also receive more sunlight for the front part of the bed than if front and back were level. The whole frame of the bed should be banked round with the dirt thrown out, or better with fresh stable manure, which will help to keep it warm and will make a bank to drain away any surface water, which, being very cold in the spring, would, if allowed to penetrate the bed, tend to chill the heat of the fermenting manure, and consequently check the growth of the young and tender plants, even if it did not generate that great enemy of all young plants, fungus or mildew, causing them to rot or “damp off.”

[Illustration: Illustration showing the manner of constructing a hotbed above the surface of the ground.]

Or, if there is plenty of fresh stable manure at hand, it can be corded in a pile two feet high and extending a foot wider than the sash frame on all sides; and when the frame has been put in position on the heap, the manure should be carried up on the outside nearly to the top of the boards, making a warm jacket for the plants within. A portable frame of boards is made for the sash to rest on, twelve inches high at the back and eight inches in front. This style of bed does away with any digging and secures good drainage for the bed. It would probably be the most satisfactory way for the gardener, who is also a farmer, as the bed can easily be removed as soon as it has served its purpose for the season, and the manure, which has become well rotted by this time will make an excellent compost for corn, melons, celery, etc. The frame and sash can also be set on a good piece of ground in the fall and filled with young lettuce plants in the early part of October, which will furnish salad throughout the winter.

The manure and litter which are to produce the heat for the bed should be thoroughly forked over and heaped together a week or ten days before the beds are to be started. While a large proportion of the material should be fresh horse stable manure, where a large quantity of heating material is needed, it can be mixed with any litter obtainable, such as straw, leaves from the woods, weeds, cut fodder, or anything that will furnish bulk and that will decay rapidly, and, by decaying, produce heat; when the material has all been gathered and heaped solidly together, a good sprinkling with water, hot, if possible, will aid in starting the fermentation. In about a week or two, when the heat of the heap has gone down to 95° or 100°, the manure should be placed in the beds and well trampled down; it should come up to within eight inches of the front of the frame and should be covered with about three and a half or four inches of fine, rich soil. It is a good plan to sift the dirt through a coal sieve, as it then makes a fine bed for the seeds and young plants.

Place the sashes on as soon as this is done; handling the manure and repacking it will produce some fresh heat and it will still be too warm to sow any seed, but the heat will destroy such weed seeds as may be in the soil, and the steam and gases arising from the manure will tend to put the soil in the finest possible condition for forwarding the growth of the young plants. A thermometer should be placed in the soil of the bed every day or two, to see if the temperature has fallen sufficiently to admit of sowing the seeds. As soon as the temperature has fallen to about 75°; or, if no thermometer is at hand, as soon as the top sod is only perceptibly warm to the palm of the hand, the bed should be sprinkled, and as soon as this has dried off a little, rake it up thoroughly and sow the seed. The seed will produce finer and stockier plants if sown in drills about six inches apart, which will admit light and air to the roots of the plants, and will permit a weekly hoeing. In planting seeds, the depth of their covering should be about five times the diameter of the seed, and this covering should be firmly packed around them after planting. The starting and planting of these beds must be calculated, so as to have the plants ready to set out as soon as the garden can be worked. In this vicinity (Philadelphia) the first sowing of cauliflowers, lettuce, beets and early cabbage should be made about February 15th, or even earlier, depending on the forwardness of the season or of your own particular garden. The plants will then be of a suitable size for transplanting by the time the early part of the garden has been plowed. If the sashes are covered with old carpets or straw on cold nights, it will be a great saving of the heating power of the manure and will prevent the young plants from being chilled. The young plants should be treated to fresh air whenever the outside temperature is not too cold, that they may not become “drawn,” or “spindle up” into long, slim stems. As planting-out time approaches, the young plants should be left uncovered as frequently as is safe, that they may become sufficiently hardy not to miss the covering when removed to the open ground.

Tomatoes, peppers and egg plants and a second sowing of early cabbage should be sown in the same manner about the middle of March. If a few extra early plants are wanted, they can be transplanted into the earliest beds when the cabbage and other plants have been set out in the garden, and the sash again put on. If some sweet potatoes are buried about two inches deep in the dirt of one of the cabbage frames, and kept warm, they will produce a fine lot of sprouts, or, as they are called, “sets,” which can be broken off and planted in the garden when the weather has become sufficiently warm. If a number are wanted, or there is danger of their growing too large, they can be taken off and “heeled in” in another sash until planting time, and the potatoes put back again, as they will produce two or three crops of the sets. Or a hill of cucumbers can be planted in the centre of each sash as a second crop, and by the time it would be warm enough to leave them uncovered, these will have filled up the frame with bearing vines, gaining at least a month on those planted in the open ground.

While the cabbage, cauliflower, beets and lettuce may be planted out as soon as all danger of frost is over, the tomatoes, peppers, egg plants, etc., should not be set out until the thermometer stands at over 60° all night, or until the oak leaves are as large as a five-cent piece. In a small hotbed it is best to have a partition between each sash and the one next to it, so that such as are tender varieties may be kept warm and the more hardy cabbage may have plenty of fresh air, for if the latter should become “drawn,” all the advantages of an early start will be lost and the plants may become entirely worthless.

Sowings of seeds for early plants may be made in the same manner as above described for hotbeds, in cold frames, which are the same without the artificial heat germinated by fermenting manure, depending solely on the heat of the sun and the protection of the sash to forward the plants. They can be planted about two weeks later than the dates given for the respective vegetables in hotbeds, and the plants will be ready for setting out about the same length of time later than those raised with the artificial heat. These frames can also be used for wintering over a few fall-sown cabbage plants, which are useful in a very early season and can be kept full of parsley, lettuce, etc., making a pleasant variety of greens for the table during the winter.

As soon as it is warm enough to dig them and bring them into fine order, seed beds should be made in a sheltered spot of the garden, for the sowings of late cabbage and celery, which will be spoken of in detail under the special directions for growing these vegetables.

TOOLS.

Although not positively necessary, it is of great advantage to have a variety of tools for thoroughly working the soil and to facilitate the labor of planting and harvesting the crops, and exterminating weeds. If, however, the garden is as well cultivated as it should be, there will be no chance for weeds to start, as they will all be destroyed in their earliest stages.

While there is a general assortment of tools on every farm suitable for use in the garden, I will give a short list of some especially adapted for use in the kitchen garden and the modes and purposes of using them.

First is the PLOW. For the first plowing in the spring, and for the general plowing in the fall, I use a large two-horse plow, which takes a generous slice and will put the manure down as may be wished and return the enriched soil to the surface in the spring, again turning in another coat of manure, if it is to be had in sufficient quantities to do so. So long as the fresh manure does not come in direct contact with the young plants, I do not think it is possible to put in too much, at least in the first three years of the garden. In my soil, which is rather heavy, I plow six to eight inches deep; in light soil I would plow deeper, as the roots penetrate it much more rapidly. For working among the strawberries and permanent rows of small fruits, I use a light one-horse plow, with a swingle tree just wide enough to permit the horse to move freely; this plow is also used in plowing out the potatoes and in preparing the ground for a second crop. If the share is kept sharp, as it always should be, it will be found very useful in the cultivation of the berries, melons, etc., as with a good plowman it will go deep or shallow, or will slip around some point to be missed much easier than the cultivator.

When these plows are not in use I give the mould-board and all bright parts a coat of thick whitewash; this keeps them from rusting, so that plowing a single round leaves them bright and shining. A coat of this on all bright tools, spades, hoes, etc., in the fall, will keep them in the best order through the winter, so that no time will be lost getting them into good working condition in the spring.

A good companion to the light plow is a one-horse HARROW, of a V shape, with long, slender teeth. It is a splendid tool for making a good, deep bed of fine earth for seed sowing or setting out small plants. Where more land has been plowed than is needed for immediate planting, I run over it with this implement when working the balance of the garden, so keeping it clear of weeds and in fine condition for planting. It is especially convenient to have the ground in this shape for planting cabbage, celery, tomatoes, etc., as you can take advantage of a good shower to set them out while the ground is thoroughly wet. My plan is to commence planting when the rain begins, the fresh plants having the full benefit of the shower.

The ROLLER and the Harrow generally go in succession, and a light one-horse roller will be found very convenient, but the large farm roller will do equally good work where one is at hand and there is room for it to be used. A small hand roller, about three feet in width, for rolling in small drilled seeds, such as beets, onions, turnips, etc., and by which the dirt can be settled over a row of peas or corn when only a few rows are planted at once, will many times repay the labor of making it. A piece of six- or eight-inch drain pipe, with the bell knocked off, an iron bar run through the centre for an axle, and the whole inside filled with mortar or concrete and allowed to get perfectly hard, will make as fine a hand roller as need be, or one can very easily be made from a smooth section of a tree trunk. This implement would probably be much more useful than the one-horse roller. It always pays to roll ground every time it is plowed, and too much stress cannot be laid on the value of firmly compacting the soil around freshly sown seed.

The CULTIVATOR is the most important and most frequently used tool in the garden, and should be of the best make obtainable. I consider the IRON AGE or PLANET, JR., the best, they having a light iron frame which is very strong without being clumsy; the spreading bars close inward, so that they do not catch or interfere with the plants in narrow rows, and admit of working rows not more than two feet apart, so that the ground can be cropped to its full capacity. They have a variety of adjustable and reversible

teeth, including plow, shovel and cutting teeth, which will throw the soil to or from the row, or leave it loose and level; in light soil this cultivator will loosen and let in the air seven or eight inches deep. These adjustable teeth are all sharpened at each end so that they can be turned around, so saving the number of times that they will need grinding, as both ends can be used and one grinding suffice where it would take two in the ordinary style of teeth. When worn out, the whole set can be taken off and new ones purchased at a very moderate cost. This part of the implement should be well watched and the teeth kept in good cutting condition, as it will not only kill the weeds a great deal more thoroughly when sharp, but will also be much lighter of draft.

Next to the cultivator comes the WHEEL HOE or hand cultivator. By the use of this implement, roots and small growing vegetables, such as onions, beets, parsnips, lettuce, radishes, parsley, etc., may be planted and thoroughly worked in rows from six to twenty-four inches apart; thus more than doubling the amount that can be raised by horse cultivation. A good implement will not throw dirt over the small plants as the larger cultivator does, so that the rows can be worked closely enough to avoid having to be gone over with the hand hoe after the thinning out has been done. In my experience, I have found that a man can hoe more ground and do it twice as deep and well in one hour with one of these implements than he could do in a day with the old style hand hoe. There are numerous styles of wheel hoes on the market, but the only good one that I have ever seen is “Lee’s Wheel Hoe,” which is made in Philadelphia under the patent of the inventor, who is himself a prominent trucker. It is strong, light and well built; it has five sharp, finger-shaped teeth back of the wheel, which loosen and pulverize the soil, and a broad hoe blade behind, which travels beneath the surface, turning the soil over and cutting off under ground any weeds which may be in its track. When the soil is in good order, it leaves it as smooth and fine as would a steel rake. To obtain the best results with this tool or with the cultivator, you should go through each row three or four times, so as to pulverize and work over the soil thoroughly. The hoe blades are of different widths, for working rows of different widths, a set of three going with each implement. These hoes can easily be sharpened by any blacksmith. Keep them well sharpened, and it will be surprising to note how much less muscle it takes to push them and how much better the work is done. I have tried several different makes, as I work an acre or more each year with one of these hoes and a “Fire-fly” hand plow, which is run before the wheel hoe when the ground is very hard, and Lee’s is the only one that works satisfactorily. When the ground is in the best condition a man can hoe the acre in a single day, so that it will readily be seen what a labor saver it is.

The FIRE-FLY HAND PLOW just spoken of is a very convenient tool for making drills, and will plow out a furrow from one to four inches deep, for sowing peas, corn, beans, etc., and coming back alongside of the open furrow will cover them nicely, not taking one-quarter of the time necessary to make the drill with a hoe and cover with a rake, as it is ordinarily done. It is also very handy to strike out a furrow in this way when planting strawberries, cabbages, tomatoes, etc., especially where two are employed on the same work, as one can strike out the furrows, and drop a plant where each one is to stand, while the other, following, sets the plant with one hand and with the other pulls in and places the loose covering dirt, and finally tramps the soil firmly round the new-set plants with his feet. These two last-mentioned tools are very useful in the ordinary small garden; they enable the work to be done much more quickly and very much more thoroughly than is often the case, the spring spading being generally the only good stirring the soil gets in the season.

A SEED DRILL is a very handy tool, but it is quite expensive. In the kitchen garden there is seldom more than one or two rows across the garden to be sown with any one kind of seed, and this can be done almost in the time it would take to adjust the drill, although the drill works a great deal more evenly than the seed can be sown by hand. On a farm where root crops are raised for soiling, the drill will be a measure of economy, even for a single season, and can readily be used in the garden. The combined implements, with plowing and hoeing attachments, are “a delusion and a snare;” if you want a tool that will do good work, and will not get out of order or break, do not have it “combined” with anything else.

Of HAND-HOES, STEEL RAKES, TROWELS, SPADES, SHOVELS, ETC., there should be enough to furnish each man employed, as it is frequently desirable to have all hands working on the same job. Of these, the hoes, spades and trowels should have an intimate and frequent calling acquaintance with the grind-stone. It is much easier to work with a _sharp_ hoe or spade, and the work is much better when done.

There should be a good stout cotton LINE, long enough to reach across the garden, and a reel to keep it on is a great convenience, as it takes such a short time to wind it up that there is not the same temptation to leave it out all night. A good cotton line, carefully housed, will last for years, and is one of the most important requisites in the garden. Neatness is one of the essentials of good gardening, and I have never known a gardener successful who was “hit or miss” in laying out his rows; every plant must be squarely in the row to admit of close working with the cultivator. If it is necessary to keep a few inches away from the row to avoid cutting the stragglers, either the soil is not loosened around the plant as it should be, or it has to be gone over with the hand hoe,

which consumes time in a large garden.

PLANTING THE GARDEN.

It is common in most gardens to plant blackberries, raspberries, currants, etc., around the fences. This is not only a waste of half the fruit, as it can only be borne on one side, but involves much needless labor in keeping the plants trimmed and worked, and unless hoed frequently the plot becomes a harbor for weeds. The only advantage in so planting is the protection the fence affords in winter, as it catches the flying leaves and weeds in the fall, and these with the shade afforded by the fence and drifted snow make a natural protection for the roots and canes. It is not the severity of the frost which determines the hardiness of a plant, so much as its ability to withstand freezing and thawing in rapid succession. For this reason I would have the small fruits planted at the north side of the garden, especially if it be the highest part, and if there is some kind of wind-break or protection, as this will cause the snow to drift and lie longer, making a natural covering, while the slope will drain the surface water quickly away, so that it does not form hard ice around the crowns.

If it were possible, I would prefer to have no fence around the garden, as it makes it much easier to keep clean. A fence is always a nuisance and waste of ground unless absolutely necessary; but if a fence is needed, have one that will not only keep out stock, but also the gardener's most aggravating enemy, the poultry. A scratching hen seems to have an instinct which tells her as soon as the seed has been planted, and which are the hills containing the choicest varieties.

In plowing the ground in the early spring, I think it is best not to plow more than is needed for the first planting, and to plow the remainder somewhat later, when it has become more dry and friable, as it will not then become packed and hard again by the heavy spring rains. For the first planting the ground should be plowed and planted as soon as it can be got in order; the hardier vegetables will even stand a light frost, and while adapting their growth to the weather, will be ready to take advantage of the first warm spring days. I shall speak of the time of planting and sowing in the chapters devoted to the separate treatment of the different vegetables.

The following simple test will be of use to the novice in determining not only when to plow, but also when to cultivate and hoe the ground. Take a portion of the soil in the hand and try to press it into a ball; if it makes a ball and sticks to the hand it is too wet, while if it crushes hard it is too dry. In both cases, if worked in this condition, it will be left in a hard and lumpy state, that will take a long time to bring into good order. To be in good working condition the soil should crumble easily and finely in the hand, and should leave no dirt adhering to the fingers. It will not only give the best results when worked in this state, but it can also be done in half the time. Sometimes we cannot wait until the ground is in the very best order, as in a drought in summer, when it is needed for the second crop. In such a case it must be brought into as fine condition as possible by repeated harrowing and rolling; the latter is an operation too frequently neglected in the ordinary garden; every farmer knows the value of having the soil firmly compacted round the fresh-sown grain, and it is of equal value in every variety of seed sown in the garden. Where there is not room for the roller to be used after sowing a row, I always have it pressed in by the broad sole of the gardener's boot, which nature usually provides shall be of generous size. It is even more important that the soil should be firmly pressed around the roots of newly-set plants, as if this is not done the first heavy rain uses the roots as water courses, and deprived of contact with the soil, the roots rot off and the plants are stunted or die.

Among the first things to be planted in the spring are the small fruits, such as grapes, blackberries, raspberries, currants, strawberries, etc. These should all be in the kitchen garden, and with them the rhubarb and asparagus beds, where they can and will be cultivated as well as the vegetables, the soil kept loose and free from weeds, that they may devote their energies to making strong canes and bearing fine fruit, instead of wasting their strength in a continuous battle for life with grass and weeds, leaving them an easy prey to insects and disease. Those who have never given them this thorough cultivation will be surprised at the large crops and superior quality of the fruit that can be raised under these favorable circumstances. These fruits, when once planted, with the exception of strawberries, last for many years if well manured, trimmed and cultivated. They should all be at one side of the garden, where they will not be in the way of working the garden with the large plow in the spring and fall, but should have their own plowing with the small plow, two to four inches in depth, spring and fall. In the fall plowing the furrows should be turned toward the row, which will bank them up slightly and afford additional protection through the winter. In the spring this ridge can be worked down level again with the plow and cultivator, the dirt from around the crowns being drawn away with an ordinary hand hoe.

In planting the rows in the spring, the width of the cultivator and swingle tree must be taken into account. If the ground has been heavily manured the vegetables can be planted as closely as will admit of working, and allowing a good supply of light and air to the

roots, excepting melons, and other vines, which should have plenty of room in which to spread and sun themselves. Thus, peas, beets, bush beans, etc., can be sowed as closely as two and one-half feet apart, while corn, pole beans, etc., which grow as high as the horse's sides and the cultivator handles, should have the rows four or four and one-half feet apart, not only to allow of working but to admit of the sunshine and air penetrating to the roots.

WHAT TO GROW.

ASPARAGUS.

This is the earliest vegetable to be ready for use in the spring, excepting those that have been forwarded under glass. While it is quite hardy and withstands much ill treatment, nothing will better repay careful culture and generous feeding. One row across the kitchen garden would make a liberal supply for an average family. The seed should be sown where the row is to stand, and the young plants thinned out until they stand one foot apart in the row. This should be done as soon as they are three or four inches high and well started; if left longer it will be a very troublesome job. These young plants should have every encouragement of manure and cultivation, to make as strong a growth as possible; the stronger and faster they grow the better will be the size and quality of the shoots when old enough to cut. No shoots should be cut until the third spring after sowing, and then should not be cut too long the first season. The fourth and succeeding seasons it may be cut from the time the first shoots appear until the first peas and lettuce are ready to take its place on the table. Then it should be well worked and allowed to attain its full growth, that strength may be stored in the crowns to furnish the shoots for the next season's cutting. As soon as the tops begin to yellow, and the berries to ripen in the fall, it should be mowed off close to the ground and the tops burnt, taking care that all the seeds are consumed; if left on the plants all winter the seed becomes scattered, and, owing to its capacity for sending up shoots, it is a very difficult weed to exterminate. If you do not wish the labor of sowing the seed and tending the young plants, a year can be gained by purchasing the plants. The one-year old plants are preferable unless the older ones have been transplanted each year, as they are gross feeders, and become stunted if allowed to crowd each other while young. To produce the large, fat shoots, it is necessary that the seed shall have been saved from the strongest shoots obtainable, and the plants fed constantly. The best way is to cover the crowns, after the ground is frozen in the fall, with as much manure as can be spared, and work it down to the roots in the spring as soon as it can be forked in; or, if there are several rows, the manure could be placed on them thickly and the soil ridged over it for the winter by throwing up a couple of shallow furrows with the plow; this to be worked down with a sharp harrow in the spring. As soon as it is dry enough in the spring, the soil and manure of the bed should be lightly forked over with a manure fork and the surface raked fine; the reason for using the stable fork is that the tines are slightly curved, and if the handle is held in a nearly horizontal position the bed can be dug down to the roots, and the fork will slide right over the tops of the crowns without injuring them. Where more than one row is desired they should be planted about three feet apart, to admit of cultivation and free access to the beds for cutting. An advantage in sowing the seed is that the crowns are naturally established at a proper depth. In planting the crowns obtained from the nursery-man they should be set at a depth of three or four inches at the most; not one foot under the surface, as is the common practice of truckers. Market gardeners cut the shoots as soon as the tips appear above the surface, so that their shoots are blanched for their whole length; but they do this at the expense of the table quality, as only the tips are edible in this way, and even these taste very much like old hay to any one who has been accustomed to the richness and delicate flavor of shoots cut at the surface when they are from three to four inches in height; this method has also the advantage of not destroying the young shoots just coming up, as the stalks are only cut an inch or so underground, and the knife only reaches the one intended to be cut. If the appearance of the blanched asparagus is desired, it can be much better obtained (that is, with less sacrifice of quality) by placing four or five inches of hay, straw or other litter over the crowns, which can be pushed away from the stalk when cutting and easily replaced. There is another strong reason for not following the deep planting, as usually practiced, and that is, in having your crowns so much nearer the surface they feel the warming and growing influence of the sun sooner in the season, and you are able to have your asparagus for cutting a full week earlier than your neighbor who plants deep.

VARIETIES OF ASPARAGUS.

As mentioned above, this succulent is capable of great improvement by careful selection of seed from the best stalks. The old Purple Top variety is no longer grown, its place having been taken by the larger shoots and better quality of the variety known as Conover's Colossal. This latter, however, has been propagated so extensively and with so little care that it is now almost impossible to obtain seed or plants that will produce the splendid shoots of the original stock. Of the new varieties Barr's Mammoth seems to be the most promising, and as grown in some fields in the vicinity of Philadelphia produces shoots which will average nearly an inch in diameter.

BEANS.

The first planting of snaps or dwarf bush beans can be made when the first planting of peas and beets are sown, but will not do as well nor produce beans of as fine quality as those planted about two weeks later, when the weather has become warmer and more settled. These yield very abundantly, and a drill fifty feet long will produce as many as can be used in a large family. While planting in a drill, for the sake of convenience and quickness in planting, the seed should be dropped in hills about ten inches apart and five seeds to a hill. If the beans are kept picked closely, the plants will continue longer in bearing, and they may be had throughout the season if successive plantings are made, though the pole snaps are to be preferred through the summer and fall, for their greater bearing qualities and the ease of gathering them. In both the bush and pole snaps, care should be taken to secure varieties that are entirely stringless, as they are not only much easier to prepare for use, but are much more tender. The different “Wax” varieties are very fine, but the bush beans of this class have not done well in this locality for the last three seasons, the pods being covered with a species of black spot or rot that spoils fully two-thirds of them.[1]

The pole beans should not be planted until the ground is thoroughly warmed in the spring, or until the thermometer stands over 60° all night. It is quite common to plant these with poles 8 to 9 feet in height. I think this is a mistake, as no ordinary picker can reach higher than about six feet to advantage, and as the vines grow to the tops of the poles before commencing to fruit, both beans and time are lost. The poles should be set in rows four and one-half feet apart and two and one-half to three feet apart in the rows. Two hundred poles of Limas will furnish an ample supply throughout the season, and will ripen a bushel of dried beans for winter use as well. Twenty-five poles will furnish an ample supply of snaps, though we allowed one row across the garden in the diagram given, the surplus being allowed to ripen for winter use. Where the saving of room is an object and the ground has been well manured, these pole snaps can be planted in the hills of corn, and allowed to use the stalks as poles; they will produce a good crop, but not nearly so many, nor are they as easy to pick as when grown on the poles. For this purpose they should be planted with some strong growing variety of corn, such as Stowell’s Evergreen or other late variety.

The white soup bean, that is dried for winter use in various ways, including the famous “Boston Baked Beans,” is generally grown by dropping one or two hills between each hill of corn, and instead of picking them, the whole plant is pulled up in the fall, and the beans thrashed out with a flail when dry. For Limas and pole snaps, the poles should be set by the aid of the garden line, and where any pole is bowed or crooked it should be planted so as to bring it in line with the row, lengthwise, as nearly as possible, that they may present an orderly appearance. In setting the poles, make a hole from one to two feet deep by driving the sharp end of a crowbar into the ground, place the butt end of the pole in this hole and ram it firmly in its place; then put one or two shovelfuls of compost around the base of the pole, and with a sharp steel rake make a hill of fine dirt over the compost. Five or six beans should be planted to each hill, but if all grow should be thinned out to two or three. If the young plants do not climb the poles readily at the first start, they should be trained up and tied till they begin to take hold for themselves. Be careful, in planting Lima beans, to push them into the soil with the eye down, for, as the first leaves are quite large and heavy, it assists them materially in breaking through the soil to plant them in this manner.[2]

The Limas may be brought into bearing somewhat earlier in the season by placing pieces of sod, cut four inches square and about three inches thick, grass side down, in the hotbed, and planting four or five beans in each piece; if this is done in the latter part of March they will be of good size by the time it is warm enough to plant them out, which is done by planting the piece of sod at the base of the pole, in hills, as prepared for the seed. If the end of the vine is pinched off when it is about four or five feet up the pole, it will assist the lateral shoots in blooming early, and consequently produce beans earlier, though, like all forcing methods, it will, to some extent, lessen the vigor of the vine, and most likely, to some extent, the amount of the crop.

BUSH BEANS--_Golden Wax_.--This is one of the best bush beans; it matures early; the pods are of very handsome appearance, brittle and entirely stringless; it is a good bearer and makes an excellent shelled bean for winter use.

Best of All Dwarf Bean.--This is a green-podded bean, and is probably the best for the first planting, as it is not only very early but also very productive; the pods are six inches long, entirely stringless, very fleshy and rich flavored.

Champion Bush Bean.--This is a strong grower, attaining about fifteen to eighteen inches in height, and an immense cropper. The beans can be used as string beans in the green state, but its chief quality lies in the superiority of the beans when dried, and the large crops which it produces when grown for winter use.

[Illustration: BEST OF ALL DWARF BEAN.]

[Illustration: CHAMPION BUSH BEAN.]

POLE BEANS, SNAP VARIETIES--_Golden Wax Flageolet_.--This bean is of recent introduction, and is worthy of all the praise that has been bestowed upon it; it is a tremendous bearer, and is almost as early as the dwarf wax varieties, the pods are much larger, being seven to eight inches long, round and very fleshy; they are entirely free from strings and of the finest quality. Unlike the other pole beans, it begins to produce beans at the bottom of the pole as soon as it starts to climb; and if these are used as they mature, it will continue in bearing the entire season.[3]

White Creaseback, or Best of All.--These for early and the _Lazy Wife's_ for late are the best of the green-podded pole beans. The pods are about six inches in length, thick fleshed, and of very fine quality. The Creaseback is very early and matures its crop in a short time, thus making it a very profitable variety for market. Both varieties are very productive, entirely stringless, and of superior flavor.

[Illustration: CREASE BACK POLE BEAN.

LAZY WIFE'S POLE BEAN.]

LIMAS--_Extra Early Lima_.--This variety matures very nearly as early as the Small Lima, while the beans are more nearly the size of the late Lima; the quality is very fine and the quantity large, as it bears the pods in clusters of four, with four to six beans in a pod.

Dreer's Improved Lima.--This variety is early and very productive if measured in the green state; the pods are smaller than in the ordinary Lima, but the beans are very plump, and are so close together in the pods as to crowd against each other. As a green bean it is very early, and shells out more quarts to the basket of pods than the larger varieties; but the quality is not as fine, and in the dry state the beans shrivel up till they are only about the size of dry bush beans, and are not nearly so good as the other varieties.

King of the Garden.--This is a new variety, in which the green beans are of unusual size and very fine quality. I have seen half an acre planted with this variety which I am sure had at that time more than twice the quantity of beans that could be grown on the same ground of the ordinary kinds; vines were loaded with clusters of pods seven to eight inches in length, and it was no rarity to see them with five very large beans in a pod. From its great productiveness and the fine quality of the beans, it deserves the first place among the Limas.

BEETS.

Seed of these should be sown when the first planting is done in the spring. They may be had still earlier by planting the seed in a hotbed while the ground is still frozen, and transplanting them to the garden a week or so after the cabbage and lettuce have been planted out. Care must be taken in transplanting the young beets, that the tap-root does not get broken, or it will make a number of fibrous roots instead of the large, smooth globe desired for the table. When the seed is well up, the plants should be thinned out until they stand six or ten inches apart, as the size of the variety demands. A second sowing should be made about June 1st, and the main sowing about the 15th of July or 1st of August, to raise roots for winter use. These frequent sowings are necessary to have the beets of fine quality; as the roots get older and larger they become "woody," or hard and fibrous, and exceedingly tasteless. Where the season is short, or there are prospects of a dry fall, the second sowing should be large enough to produce the winter crop, as the later one may fail to mature in time. The beets may be stored and the flavor retained by the method described for pitting turnips, and will keep in good order until spring.

The Bassano and other light beets are of quick growth and are tender and palatable while young, but are of coarse texture and not nearly so fine in appearance when cooked as the blood beets. The blood beets retain their deep, rich color, while all the light-leaved or light-stemmed varieties are colorless, or nearly so, when cooked. It certainly adds to the attractiveness of a dish for the vegetable to have a handsome appearance when cooked.

The seed should be sown in drills, from twelve to eighteen inches apart, if to be worked with the wheel hoe; if for horse culture, two and a half to three feet will have to be allowed between the rows. The ground should be raked clear of clods and made as fine as possible. A drill is made by drawing the rake or hoe handle along the line. The drill should be about an inch in depth and the seed should be dropped about two inches apart, thinning out to six or eight inches apart when well started, and if it is desired, the thinnings can be transplanted to another row. If no small roller is at hand, the drill can be covered and packed by the same operation, by removing the line and shuffling along the row with the feet placed in a V, the forepart of the foot drawing in the fine soil

while the heels at the point cover and press the dirt down upon the row; the foot, of course, is only moved a few inches at a time, but with a little practice the rows can be covered in this manner quite rapidly.

VARIETIES OF BEETS.

ECLIPSE.--This is a very early beet, of quick growth and very fine quality. As the leaves of this variety are small and the stems short, they can be grown quite closely together. The roots are perfectly smooth, regular, globe shape, blood-red skin and flesh, fine grained and very sweet when cooked.

EDMAND'S EARLY TURNIP.--This variety is turnip-shaped, that is, tapering more gradually below the shoulder than the Eclipse; the foliage is short and stocky, enabling a heavy crop to be grown, as they can be grown as closely as six inches apart; the flesh, of a deep blood red, is of the finest quality.

[Illustration: EDMAND'S EARLY TURNIP BEET.]

[Illustration: BURPEE'S IMPROVED BLOOD TURNIP BEET.]

BURPEE'S IMPROVED BLOOD TURNIP.--This beet attains quite a large size and is very smooth and regular in appearance; the flesh is deep blood red and of fine quality, whether eaten in summer or stored for winter use; it is one of the best varieties for the latter purpose, and should be sown as described for the winter crop.

CABBAGES.

Of this vegetable two distinct crops are raised in every garden, while many gardeners, by successive sowings and the use of several varieties, have them fit for use constantly from early spring until fall, and throughout the entire winter by storage. In the ordinary garden the same result may be obtained by planting larger quantities of the early and summer varieties, and cutting them as wanted for use, as most of them will stand the whole summer without bursting or going to seed, and by early fall some of the winter cabbage will be large enough for use.

EARLY OR SUMMER CABBAGES.--The seed for these should be sown in a hotbed from the 1st to the 15th of February. As soon as the plants are large enough to set out they should be given plenty of air, and should be gradually hardened off until they are able to stand the cool nights without protection; but they should not be allowed to freeze. Treated in this way they will be ready for planting out as soon as the ground can be worked. In making this sowing I would have it of two kinds--some of a small, hard-heading, early variety, and about twice as many of a larger-heading summer kind. These latter are described as second early in the seed catalogues.

These early cabbages need very little care except to have frequent and thorough cultivation, as they are comparatively free from insect pests as long as they make a healthy growth. If attacked by the black fly or green worm, they should be dusted with land plaster or slug shot early in the morning, while the dew is still on them. The soil around these and all other crops that depend on quick growth for their superior qualities, must not only be cultivated, to kill the weeds, but must be kept loose and well stirred, to admit the air to the roots of the plants; it must not be allowed to lie heavy and packed after dashing rains, but should be stirred up as soon as dry enough. The rows may be as close as can be worked with the cultivator, say about three feet, and the plants about one and a half feet apart in the row, or even closer, if the variety grown makes but small heads.

LATE OR WINTER CABBAGE.--As soon as the ground becomes warm in the spring, or early in May, a seed bed should be made and sown with the late varieties of cabbage and celery, or the seed may be sown in drills in the garden; the seed being sown in very thinly, so as to produce plants standing about half an inch apart in the row. Where it can be done, it is best to sow the seed in a special bed or cold frame, where they can be watered and nursed to a good size by the time they are wanted for planting. The Flat Dutch and Drumhead types are the best for this planting, though many prefer the Savoys, claiming a superior delicacy of flavor, on account of their having more leaf surface to the number of ribs or veins; they are not, however, nearly such sure headers, nor are they as good keepers when buried.

It is important to get the seed sown early, that the plants may be had of good size by the middle of June, though they will make a partial crop if planted as late as the middle of August. As these varieties make larger heads than the summer cabbages, they cannot be planted so closely; the rows should be 3 to 3½ feet apart, and the plants 2 to 2½ feet apart in the rows. These can be planted and grown between the rows of early peas, corn or potatoes; but I would prefer to wait until the first crop of corn be cleared

off the ground, as it can then be brought into much better condition. It adds greatly to the labor of harvesting the first crop when the ground is so closely planted, and the soil is apt to become hard and packed before it can be cultivated again.

When possible, the young cabbage plants should be set out directly before or after a good rain, but if there is no prospect of rain, they should be planted in the evening and a tincupful of water should be poured in each hole before the plant is set in; then draw the dry earth up around the stem and pack firmly around the plant; this will enable them to withstand at least a week of dry weather. If the drought should continue longer, or they do not come up fresh in the morning after a flagging day, they must be watered in the cool of the evening, when the plant will have the benefit of the water all night. It is waste of time to water them while the hot sun is shining, unless they can be shaded with papers, old pans, etc.

As soon as they become well established, the soil around them must be carefully loosened and cultivation begun. To obtain the best results they must be cultivated frequently and deeply. It is a common sight in some gardens to see the cabbage with stems two feet high and a small bunch of wormy leaves at the top; a closer examination will show that the soil is hard and trampled, and that the plants have been left to grow as best they may, while in the well-cultivated garden the stems are short and the heads are large and solid.

The young plants of late cabbages are generally infested, while in the seed bed, with a small black fly, which greatly checks their growth, and sometimes entirely destroys them. These can be gotten rid of, or better, entirely avoided, by the application of dry road dust, soot, slug shot, or land plaster, dusted on the young leaves early in the morning, while the dew is still on them; this should be repeated every two or three mornings until the fly is exterminated and the plants have grown to good size. When the plants have been set out and are nearly ready to head, the green cabbage worm makes its appearance, and if fine marketable heads are desired this pest must be destroyed. Many remedies for this are given, most of which are ineffectual. It is best to sprinkle well with tar water or alum water, taking care to get it well down into the centre of the loose leaves, using an ordinary watering pot for the purpose; if a garden syringe is at hand, it can be thrown into the plant much better than by sprinkling. To make the tar water, the tar is put in a barrel of water and well stirred; then, when it has been allowed to settle, the water from the top is dipped off and used. It should be strong enough to have quite a decided taste. The alum maybe dissolved in the watering pot, about one tablespoonful to the gallon, and stirred till dissolved. See that the solution gets well into the centre of the loose leaves just below the head, as this is the favorite place of attack by the worms.

The cabbage is quite hardy and will stand considerable frost in the fall without damage, being rather improved in quality by it. By the third week in November they should be put in pits or the vegetable cellar; or, where these conveniences are not at hand, they should be pulled up, root and all, the outside leaves wrapped closely around the head and stood side by side, on their heads, on a well-drained piece of ground; they should be placed in a long row two or three heads wide, and where a good many are to be buried or gotten out at once, two additional rows may be placed on top of these, as shown in the illustration.

FIG. 2.

Illustrations showing the manner of storing cabbage for winter use. Figure 1 showing three rows of heads and Figure 2, five rows. C. Heads of cabbage. S. Soil banked over the heads. D. Drainage ditches to carry off the water.]

Dry soil is then thrown on these heads to the thickness of five or six inches and the roots left sticking out of the top; this covering should be firmly packed, to prevent the entrance of water, and a small gutter should be dug round the heap to carry it off. If, after the cold weather has set in and the ground is slightly frozen, the heap is covered with three to four inches of corn fodder or litter, it will prevent the covering from freezing so hard, and will greatly lessen the work of getting out the heads when wanted for use. When heads are wanted, one end of the bank is opened and as many taken out as are desired; the open end is then carefully covered over with soil. Too many should not be taken out at once, as they retain their flavor better when buried in this manner than when kept where they are exposed to the open air. If it is desired to save some of the best heads for seed, the roots of the plant must be buried as well as the top; they can then be replanted early in the spring and a cross cut made in the top of the head to assist the flower stalks in bursting through, as the heads are sometimes so tight that they will rot before bursting.

[Illustration: EXTRA EARLY EXPRESS CABBAGE.]

[Illustration: EARLY JERSEY WAKEFIELD CABBAGE.]

EARLY VARIETIES--_Extra Early Etampes._--This cabbage is the earliest heading variety that I have ever grown. The heads are small but round and very solid, and it is ready for use nearly two weeks ahead of the other early varieties.[4]

Early Jersey Wakefield.--This has long been the chief favorite for the general crop of early cabbage, and is deservedly popular, as it is sure to head when the seed is good; the heads are of good size and shape, and the quality is fine.

Early Summer.--This succeeds the Wakefield, and has heads about twice the size of the latter; they are round, very solid and slightly flattened on top; it has few outside leaves and can be planted closely; this variety matures about two weeks later than the Wakefield, and a month after the Etampes.[5]

VARIETIES OF LATE CABBAGES.

At the head of these I would place BURPEE'S SUREHEAD, which has done so well for me since I began planting it, never failing a single season, that I now plant my whole crop of it, instead of planting two or three kinds as formerly, to guard against poor seed or a bad season. It is an improved type of the Premium Flat Dutch, to which it is superior in the evenness and regularity of its heads and the "sureness" of every plant to form a fine head. With me the heads average larger than the Flat Dutch, are rather more rounding in shape and are of the finest quality.

[Illustration: EARLY SUMMER CABBAGE.]

[Illustration: BURPEE'S SUREHEAD CABBAGE.]

[Illustration: BURPEE'S SHORT-STEM DRUMHEAD CABBAGE.]

SHORT-STEM DRUMHEAD.--This variety produces on extra short stems, only a few inches in height, very large solid heads, often twenty-five pounds in weight. It is from this kind that the very large heads seen at the county fairs in the fall are grown, and where the ground is heavily manured and well cultivated enormous crops of this variety can be grown; it is of fine quality, very solid and an excellent keeper.

[Illustration: The Vandergaw Cabbage

The Best Second Early and Summer Cabbage.

Equally as Good For Winter.

COPYRIGHTED 1887.

BY W. ATLEE BURPEE & CO PHILADA]

DANISH BALL HEAD.--This variety has only been recently introduced, but bids fair to take a leading place as a winter variety; the heads are quite round and very solid; they are of medium size and very handsome appearance, which make it a good market variety, while the quality fully equals its good looks.

CAULIFLOWER.

The culture of this vegetable is the same as that for cabbage, in most respects, but it is not a certain crop in our changeable climate and hot, dry summers. It likes plenty of moisture, and if placed in a rather wet location or in a bed where it can be frequently watered, it will be much more certain to produce fine heads. Its superior quality and the high price that good heads command make it a most desirable crop to grow wherever it will do well. I have always found the short-stemmed, extra early varieties the best ones to grow, and as in the ordinary season but about half of them produce heads under ordinary garden culture, the rest of them maturing throughout the summer and fall, it is almost a continuous crop. The seed should be sown as early as possible, in the hotbed, and great care should be taken that the plants do not become either stunted or drawn, as none but the strong, healthy plants will produce good heads. It will greatly improve the appearance of the heads if some of the broad outside leaves are broken half through the stems and the tops bent over the heads while forming. This will blanch and keep them of that pure whiteness so attractive in this vegetable as grown by the market gardeners. The heads should be cut for use or sale as soon as they have reached their full size and before the buds begin to uncurl, as this spoils both the appearance and quality of this, the finest and most delicately flavored of the cabbage family.

VARIETIES OF CAULIFLOWER.

EXTRA EARLY DWARF ERFURT.--This is the best strain for general use; there are usually two or more grades of this offered in seed catalogues, but the best should always be purchased, even if you can only buy a single packet; by taking extra care of it you can make every seed count. This variety is quite early, has short stems, and makes good-sized heads of the best quality.

[Illustration: BURPEE'S BEST EARLY CAULIFLOWER.]

EARLY SNOWBALL.--This variety is quite early and makes fine large heads, of handsome appearance.

BURPEE'S BEST EARLY.--I have only grown this one season, but found it all that it was represented in earliness and good heading quality. Owing to a drouth early in the spring, the heads were not of large size; the quality was fine, and I think it bids fair to be one of the leading varieties.

CARROTS.

These are ordinarily little used as table vegetables, but will be found very palatable as an ingredient of soups and stews. They are very easily grown, the seed being planted in drills and the plants thinned to six or eight inches apart. The seed should be sown in April or May, and they will be ready for use early in the summer. For winter use they should be stored in the manner described for beets and turnips; they will retain their quality throughout the winter, and form a pleasant variety in the winter supply of vegetables. The rich yellow and red-fleshed varieties are the most popular, and retaining their bright colors when cooked, lend an attractive appearance to the dish of which they form a part.

VARIETIES OF CARROTS.

DANVERS HALF-LONG ORANGE.--This is claimed to have the greatest bulk with the shortest length of root, and is a remarkably heavy cropper. The root is of a rich, dark orange color, and grows very smooth and succeeds in all soils. It is quite a favorite market sort.

SHORT HORN.--The flesh of this variety is very fine grained, of deep orange color and superior quality. The roots do not penetrate deeply, and the top is small, which allows of their being planted quite closely.

[Illustration: IMPROVED LONG ORANGE

S^T VALERY

DANVERS

3 OF THE BEST CARROTS]

EARLY VERY SHORT HORN, OR GOLDEN BALL.--The earliest variety; the roots are round, turnip shaped, of small size, deep color, and the quality is of the best.

OX HEART.--This variety is of large size, the roots being seven to eight inches in length and three to four inches in diameter at the top; it tapers gradually down to one and one-half to two inches at the bottom, making very little waste in preparing it for the table. It is of fine quality, while its size will render any surplus valuable for feeding to the stock.

RED SAINT VALLERY.--This is a large late variety and makes a good kind to raise for winter use; the roots grow ten to twelve inches in length and measure two to two and one-half inches in diameter at the top, tapering gradually to a point at the base. It should have deep cultivation to produce the finest roots. The color is a deep orange red and the quality is very fine.

CANTALOUPE, OR MUSK MELON.

These are universal favorites, and too frequently are not grown by the kitchen gardener, who labors under the idea that they must have a sandy soil in some particularly favored section, and that they require great skill to grow them. If a variety suited to your soil is planted and given the same amount of attention and careful cultivation as the rest of the garden receives, melons may be had in abundance from the first of August till frost comes in the fall, though when the first cool nights come they lose their fine flavor. If the garden has a southern slope, that will be the place for the melons and other warmth-loving vegetables; but they will do almost as well in the level field. The rows of hills should be five feet apart and the hills at least four feet apart in the row, to allow the vines

plenty of room to run. It is a good plan to make the hills break joint, as they will then cover the ground to better advantage. When the line is set, a hole should be scraped with the hoe or shovel where the hill is to stand; this should be six inches deep and about twelve inches in diameter. Compost is then shoveled in, two rows being done at once; two or three shovelsful are put in each hill. The dirt thrown out in making the hole is then carefully made into a hill over the compost by using a sharp steel rake, care being taken to remove all stones and hard lumps of dirt. The seed is then scattered on the top of the hill, generally from twenty to thirty seeds being planted in each hill, that there may be an ample supply for the insects and yet leave a good stand. They should be thinned out gradually, extra ones being left in until they are at least a foot in length, as the insect pests are both numerous and destructive.

The hills should not be made until it is time to plant the seed, or they will get packed and too hard for the young roots to penetrate. When the seed has been planted on the hill it should be covered with about half an inch of fine soil, sifted and crumbled on with the fingers, and the whole top patted down with the palm of the hand. The seed should be planted as soon as the ground is thoroughly warm in the spring and when the temperature does not fall below sixty degrees at night. The melons will commence ripening about August 1st, and two rows across the garden should yield from one half-bushel to one bushel daily if the variety planted is of the small Netted Gem or Jenny Lind type. These small, round melons, of the size of a croquet ball, are very prolific, and if carefully grown, the quality is very fine. Some prefer the larger melons, which fill the basket more quickly, but in my experience the small ones have been so much more prolific that the yield has been almost double in bulk on the same amount of ground. The melon rows should be gone over early every morning while ripening, as they should not be allowed to become yellow on the vines. The quality deteriorates very rapidly when allowed to ripen in the hot sun, so that they should be picked while still green. The right stage for picking can readily be told by examining the point where the stem joins the melon; as soon as the stem begins to crack away from the melon slightly, or when the little drops of red juice form round the base of the stem, it is time to pick the melon. When picked, they should be put in a cool cellar or spring house until wanted for the table.

Seed may be saved from the largest and finest-flavored melons; but if your garden is on heavy soil, or if two or three varieties are grown near together, it is best to procure fresh seed from some melon-growing district every year.

The ground between the hills should be cultivated frequently, as long as it can be done without interfering with the vine; the soil in the hills should be kept loose and drawn up around the vines with the hoe. When the vines have grown too long to allow the passage of the cultivator, the patch can be kept clean by pulling out the large weeds by hand, which can be done very quickly after a good rain. The dense shade caused by the luxuriant vines will cause the small and low-growing weeds to rot off. While the vines are still small, it will be necessary to dust them every few mornings with road dust, soot, plaster or slug shot, to destroy the flies and striped bugs that infest them. When healthy young vines suddenly wilt and droop in the hot sun without apparent cause, dig around the root of the plant with the fingers or a stick until the grub is found which has cut the plant off underground. He should be searched for and “made an example of” as soon as the first vine is discovered to be flagging, or he will proceed to eat the whole hill.

VARIETIES OF MUSK MELONS.

BURPEE’S NETTED GEM.--The finest as well as the earliest of all the small-fruited varieties that I have tried, and where a variety of melons is not particularly desired, it will furnish a generous supply of fine-flavored fruit from the first ripening until killed by frost. It is a very good keeper, retaining its good quality for nearly a week after picking, if kept in a cool cellar. This is often a valuable characteristic in the latter part of summer, as several warm days furnish two or three baskets in the cellar, which keep up the supply if the warm spell is followed by cool or cloudy days, when the melons on the vines do not ripen readily. This variety is thickly netted, the meat is thick and solid, and they run as even in shape and symmetry as a set of croquet balls, which they also resemble in point of size.

[Illustration:

COPYRIGHTED 1886. BY W. ATLEE BURPEE & CO

EMERALD GEM CANTALOUPE.]

[Illustration: 16¼-lb MONTREAL NUTMEG MELON--ENGRAVED FROM A PHOTOGRAPH.]

EMERALD GEM.--This variety has the small size and prolific bearing qualities, with the handsome salmon-colored flesh, that originated in the Surprise Melon some years ago. Too much cannot be said of the _quality_ of this melon, as I do not think there is another variety that approaches it in flavor. The vines are strong and healthy in growth and well set with melons near the hills, and

the fruit is early in ripening. The melon has a thin, green rind and very small seed cavity, almost the entire body of the fruit consisting of the rich and luscious meat.

MONTREAL GREEN NUTMEG.--A handsome variety, in which large size, regular shape and fine appearance are combined with thick flesh of the finest flavor. In shape they are nearly round, slightly flattened at the ends, very deeply ribbed and heavily netted. These melons have been grown to over thirty pounds in weight, and will average ten to twelve pounds in ordinary culture.

CELERY.

While one of the most troublesome vegetables to bring to perfection in the ordinary garden, this is one of the most desirable, as well as one of the most profitable, when well grown. The Michigan celery that is being shipped to our eastern cities in such large quantities does not seem to have lowered the price materially, but has crowded all the inferior and less finely-grown plants out of the markets, and the high express charges still guarantee a good profit to the near-by grower. When the ground has become fairly warm in the spring, a bed should be made in some shady corner for the seed; if such situation is not to be had, the seed can be sown in a spent hotbed, cold frame or other convenient place, and can be artificially shaded with fresh brush or lath shades through the hottest part of the day. Celery is naturally a swamp plant, and to make a rapid growth should have the ground as rich as possible, and also as much water as possible, without making the ground heavy and sour. The soil should not be allowed to become dry or baked, and the weeds should be pulled out as soon as they appear. This bed, and, indeed, all other seed beds, should be made very rich with well-rotted manure; not with horse-stable manure or phosphate, as both of them are dry and heating, and in dry weather would stunt or entirely burn up the young plants. The seed should be sown in drills about six inches apart, to admit of working the soil with a narrow hoe, as the continued watering will harden the surface of the bed and check the growth of the young plants. When the plants are well up they should be thinned out so as to stand an inch apart in the drills, and if the plants are ready some little time before they are wanted for setting out, they can be made more stocky and stronger by shearing off about half of the tops.

When ready to set out, I run a double furrow where the row is to be--that is, the plow is run both ways in the same furrow, casting up a ridge of dirt on either side of a shallow trench; then in the bottom of this trench fine compost or well-rotted manure is placed to the depth of one to two inches, and some of the fine soil from the sides is drawn down over the manure with a fine rake until the manure is covered about three inches. This will still leave a depth of about two inches below the surface, which will serve to draw and retain the rain water, or, in a dry time, can be flooded with a hydrant hose or irrigating ditch. Where the ground has been heavily enriched or the celery is planted as the first crop--that is, when no early vegetable precedes it on the same ground--no manure is used in the trench or furrow, which is plowed out in the same way, the additional depth assisting in the labor of earthing up for blanching. To obtain fine quality and appearance the plant should be pushed to as rapid a growth as possible from the time the seed is sown until the stalks are ready for use; if allowed to become stunted, the stalks will be knotty in appearance and bitter in taste.

For my own use and marketing I usually sow seed of two or three varieties, so that if one kind fails for any reason, I may still have a crop sufficient for the table from the other varieties, while if it is all good I have no difficulty in disposing of the surplus; this is the more easily done, as it occupies ground that has been cleared of early peas, corn, etc. Another point in not confining your planting to the one variety is that the handsome “Self-blanching” varieties are not good keepers, and as the older kinds take a long time to whiten, and a good deal of cold weather to develop the fine flavor, they are about ready for use when the early kinds are gone.

While celery is raised as a second crop and has always been considered to require frost to develop the fine nutty flavor, at least one row in the garden should be planted with a “Self-blanching” variety as early in the spring as the plants can be procured. For this it is a good plan to sow two or three drills of celery in the hotbed at the same time with tomatoes, peppers, etc., that they may be ready for planting out early in the spring. These will grow quickly before the very hot weather sets in, and in a favorable season will be ready for use by the latter part of August; if kept earthed up they will be of as handsome appearance and as crisp and fine flavored as are the older varieties in December.

For the main crop the young plants should be ready to set out by the 1st of July, though in a favorable locality they can be planted as late as the middle of August, as they spend the summer largely in making roots and do not grow much until the cool weather. As soon as the plants attain eight to ten inches in height, or, rather, _length of leaf stalk_ as they lie spread out, the earthing up should begin on all kinds of celery, although the seed catalogues will tell you that it is unnecessary in self-bleaching kinds. These latter may be bleached easily by tying the stalks together with straw or soft twine, but the earthing-up process is much more satisfactory

both to produce a compact bunch of stalks and an even whiteness in color; otherwise, the outside stalks will remain green.

My plan in earthing for the first time, or “handling,” as it is called, is to have the dirt loose and fine on each side of the row, then to stand astride the row, gather all the leaves up and hold them closely in the left hand, and with a short-handled hoe draw the loose dirt in and pack it firmly around the stalks, leaving about two inches of the tips stick out at the top. It is important to hold the stalks closely, that the dirt may not sift down among the stalks, which would either rot the heart or cause the inner stalks to become twisted and crooked. The second and succeeding bankings are done by a boy standing over the row, clasping the stems in his hand closely, while a man on each side banks up the loose dirt with a shovel; as they raise the bank the boy slides his hand further up the stalks, until, as before, all but two inches of the tips are covered. The boy moves along the row backward, facing the two men who are using the shovels; as they finish one plant he grasps and bunches another, always having a plant in each hand. This method is a great time saver, and also enables the work to be done more neatly than where the plant has to be held while the dirt is drawn from a distance with the hoe. This earthing up should be repeated every two or three weeks until it is time to store the celery for the winter. Immediately before banking, I run the light plow or the cultivator on each side of the row, which furnishes plenty of fine, loose dirt ready for use. The soil will pack better and remain in the banked form better if it is moist when handled, but must not be so wet as to be sticky, for it would then “rust” or spot the stalk. The plants should be set in rows five or six feet apart, so that there may be plenty of soil for the earthing up and room to pass between the rows when banked; the taller growing varieties will require full six feet between the rows.

About the third week in November the celery should be dug and stored; for if it is left out longer, there is danger of its being spoiled by hard freezing. If it is to go in the cellar it should be stood upright in barrels or in boxes, the sides of which are as high as the stalks are tall, so as to keep them straight and white; the roots are left on and packed in moist soil, in order to keep the plants fresh and crisp; but the soil must not be allowed to come up among the stalks, or it might cause them to rot. The root cellar must be kept cool and have plenty of air whenever it can be admitted without freezing the contents of the cellar.

[Illustration:

Illustration showing the manner of storing celery in the field for early use. C. Plants of celery. D. Banks of soil. S. Straw covering. E. Board laid on top of the straw to keep it in place.]

Another plan is to set the plants on a well-drained plot, side by side in a long row, three or four plants wide and as closely together as possible; earth banks are then raised on each side of the row about four to six inches thick at the top, and the ends closed in the same manner. The roots are packed solidly in the soil, and the banks are carried up level with the longest tops; when the very cold weather sets in the whole top, banks and leaves, is covered with straw, leaves or corn fodder, to keep the frost out. I would not recommend this method of storing unless it is expected to have the supply all used or marketed by the 1st of January. The best way to store celery is in a hotbed or cold frame, which is built two or three feet deep in the ground, as already described. The celery plants are set side by side in this, as in the boxes or barrels, and the roots tightly packed in moist soil; then the sash can be put on at nights and in the daytime can be entirely removed or slightly raised to admit air, according to the temperature. On very cold nights the sash can have an extra covering of straw or old carpet, and if there is a heavy fall of snow it can be left on a few days, until the weather again becomes warmer. Stored in this manner, it is no trouble to get the celery when wanted; it can be given plenty of air, without which it will not keep, and the late kinds, if packed closely together, will complete their bleaching. If the kinds which require blanching are not kept earthed up as the growth advances, it will be almost impossible to blanch them.

VARIETIES OF CELERY.

The dwarf and half-dwarf kinds are the best, as they are superior both in quality and appearance and are much easier grown. Of these the _Dwarf Golden Heart_ is one of the best varieties; the stalks are very thick and solid, fine flavored, and blanch to a fine white, excepting the centre, which is of a fine golden yellow.

[Illustration: NEW GOLDEN SELF-BLANCHING CELERY.]

GOLDEN SELF-BLANCHING.--The handsomest and most generally satisfactory kind that I have ever planted. I know of none that can equal it in appearance or quality; the stalks are large, straight, crisp and very solid; it is very vigorous in growth, attaining a height of one to one and a half feet, and I have had single plants of three inches in diameter. The leaves of this variety are of a beautiful golden yellow after the plant has been bleached, which adds greatly to its handsome appearance when prepared for the table. The young plants should be earthed up as soon as they are large enough to handle, and in two weeks the celery will be in the

finest order for the table, thus gaining from one to two months over the ordinary kinds. The quality is the finest and the stalks are crisp, brittle and delicious.

WHITE PLUME.--This is also a self-blanching variety, but not to the same extent as the preceding kind. In this sort the inside stalks are naturally white, and the leaves of these white stalks are variegated in the most striking and beautiful manner, which gives it the name and renders it the most ornamental variety grown. To bleach the outer stalks the plant should be kept earthed up, and it will then be ready for use at any time. It is not, however, so fine in the small state as the Golden Self-Blanching, which is of fine eating quality even when growing in the seed bed; the stalks are not so thick and meaty in the White Plume, but have a strong “nutty” flavor.

CRIMSON OR RED CELERY.--The red celery is very handsome and fine flavored when bleached, and after the self-blanching varieties is the most desirable one to grow. It grows tall and straight, is crisp and brittle, and when well blanched is a beautiful golden yellow, the ribs and ridges being tinged with crimson.

SWEET CORN.

The first sweet corn should be planted early in April, and should be of some small-growing, very early variety, such as the Cory or Minnesota. This corn will have to struggle with the frost and chilling nights, but with the aid of the ever-present worm, which inhabits each ear, will be ready for use long before any of the really fine kinds can be had. There is only one good thing that I have been able to discover in the worm’s favor in connection with his labors in horticulture, and that is the way in which he assists in ripening all the earliest specimens of the different fruits. To be sure, his efforts in this line are not always appreciated, but he is always there when you find a fruit ripening before its regular time. About the third week in April a second sowing of this early corn should be made, and at the same time should be planted some early large-eared variety, such as Crosby’s Twelve-rowed, and an equal amount of a late variety, such as Stowell’s Evergreen. Thereafter a planting should be made every ten days or two weeks, of a favorite sort, which, with me, is Stowell’s Evergreen, although I plant other kinds throughout the season, for the sake of variety. These plantings should be kept up until the 10th of July, after which the late kinds will hardly mature; but if the ground can be spared, I would keep on planting until the 10th of August, as, if the fall should be late, it will come in very acceptably. Most gardeners exhaust their supply about the middle of September, as they do not continue to plant late enough. If there is danger of heavy frost early in the fall, the corn that has well-set ears that have not yet ripened should be cut off at the ground and stacked against the south side of a fence or building; it should be stood up nearly two feet in thickness, to prevent freezing, but should not be thicker, as it will heat too much and will be awkward to handle when sorting over for the good ears. Treated in this way it will provide ears for use well into November, but of course they will not be of as fine a quality as those matured in the ordinary way.

As the earliest varieties only grow about three feet high and have the ears set close to the ground, the best way of planting them is to drop the seed ten inches to one foot apart, in drills. Sow plenty of seed, and if it comes up too thickly it can easily be thinned out when hoeing; all suckers should be broken off at the same time, so as to throw the strength of the plants into the ears.

If two rows are planted across the garden at each planting they will furnish an ample supply for the average family. If it is needed for canning or drying, an extra large planting should be made early in May, which will mature after the heavy harvest work is over and before the fall fruit is ready to preserve.

If some fine compost is placed in the drills or hills, it will help greatly to give the young plants a good start until they can reach the manure with which the garden has been dressed; where this compost is put in it should be covered with an inch of soil before the seed is sown.

The climbing snap beans may be planted in the hill with the tall-growing corn, or hills of pumpkins; squashes or cucumbers may be made in every fourth hill and every third row, although the vines will be very much in the way of continued cultivation if the ground is inclined to be weedy. Sweet corn should not be planted within one hundred yards of field or pop-corn, as the pollen will be sure to mix and spoil the quality of the table corn. It will sometimes mix at greater distances, but this distance would be safe in most cases.

VARIETIES OF SWEET CORN.

THE CORY.--This is the earliest variety known, and is at the same time superior in size and quality to the varieties which have been grown as extra early, before its introduction. It ripens nearly a week in advance of any other variety, while the ears are much larger than either the Minnesota or Marblehead. The grains are well formed to the tip of the cob, making a much handsomer ear than the

other early varieties, while in sweetness and quality it is also superior.

[Illustration: A RIPENED EAR OF THE CORY CORN.]

AMBER CREAM.--This is a medium early variety; it is a strong, vigorous grower, reaching six to seven feet in height; the ears are about ten inches in length and the quality is rich and sugary. When used on the table the grains are milky white; the “Amber” of its name coming from the ripe seed, while the “Cream” is evidently an attempt to describe its excellent quality. In planting and picking for the table, the size of the ears of this variety and of Stowell’s Evergreen should be taken into account; a dozen ears being nearly equal to two dozen of some of the smaller-eared kinds.

CROSBY’S EARLY TWELVE-ROWED does not grow quite so tall as the Amber Cream, nor are the ears as large; although called “twelve-rowed,” it frequently has only ten rows. The great merit of this kind is in its excellent quality, it being very sweet and juicy, and fully equal to any variety that I have ever eaten. It is one of the best sorts to plant after the very early kinds.

POTTER’S EXCELSIOR.--An excellent medium early variety; the ears are of good size, with twelve rows of deep grains. It is remarkably sweet and juicy, and quite productive, averaging two good ears to a stalk.

STOWELL’S EVERGREEN.--This is, in my opinion, the finest variety for late and general planting. It is strong-growing and prolific, while the ears are of large size and handsome appearance. The quality is rich and sweet, while the grains are juicy and luscious, when picked at the right stage. To have the finest corn of any variety it should be picked in just the right condition; that is, when the skin of the grain breaks at the slightest puncture, and plantings should be made frequently enough always to have a supply at this stage. The quality is inferior if it is a few days too old or too young.

CUCUMBERS.

In raising cucumbers care should be taken to procure seed that is perfectly pure, as it mixes readily with other varieties and deteriorates rapidly. The seed should be planted in hills, prepared in the manner described for cantaloupes, three feet apart in the row, and the rows 4½ to 5 feet apart. If there is not enough compost at hand to manure them, as directed in the manner of making them, the hills can be raked up a few inches above the surface and the young plants allowed to feed on the general dressing which has been applied to the whole garden; the elevation serving to give the young plants a better start than on the level surface. While the cucumber is a lover of heat and moisture, it is apt to damp off in its early stages if it should be cold and wet; the hills tending to lift the young plants up into a drier and warmer soil. A liberal quantity of seed should be sown in each hill, say twenty to forty seeds, that there may be enough young plants to survive the depredations of the striped cucumber bug and of the borers. The young plants should be dusted every few mornings with ashes, plaster or slug shot, to destroy these pests, and as soon as the plants are sufficiently large to take care of themselves they should be thinned out to only three or four plants in a hill. The first planting should not be made before the middle of May, for they will not stand cold. The cucumbers should be picked as soon as they attain sufficient size and before the seeds become developed or hard; this should be done every morning while it is still cool, and the cucumbers placed in a cool cellar. The very best way is to put them in the water in a cool spring-house; there is no place where melons, squashes and cucumbers retain their freshness and crisp, fine flavor so fully as in such a spring. If the picking is carefully attended to and all the fruit picked off as soon as large enough, the vines will continue to grow and bear all summer, especially if they are in a rather shady situation, such as among the sweet corn. A few fine specimens may be allowed to ripen for seed, but if many are left the vines will dry up and die as soon as they have ripened a crop. Where a quantity of small pickles are wanted, the best way is to make a planting about the first week in August or latter part of July. These will produce large quantities if the ground is rich, and will continue to bear until killed by frost. Like the summer crop, they should be picked every day or two, and as soon as they are of the size desired, as they will bear a great many more if not allowed to grow large; also the smaller the pickle the more attractive it is, and the more readily it sells.

VARIETIES OF CUCUMBERS.

EARLY RUSSIAN.--The earliest variety grown, and is of very good quality for table use, but only grows about three inches in length; it is very solid and has but few seeds. Its small size and earliness render it a very good variety for pickles.

EARLY GREEN PROLIFIC.--This is largely grown for pickling, and is immensely productive. The shape, quality and great bearing make it a very valuable kind.

IMPROVED EARLY WHITE SPINE.--This variety is more generally grown than any other, and is deservedly popular for both table use and for pickling. It is of medium length, and from 1½ to 2 inches in diameter; when not too old the flesh is very crisp and fine flavored.

LONDON LONG GREEN.--Grows from twelve to sixteen inches in length, is a very dark green in color, and presents a fine appearance, while the flesh is firm and crisp, and the quality excellent.

[Illustration: GIANT PERA CUCUMBER.

EARLY RUSSIAN CUCUMBER.

EARLY GREEN PROLIFIC CUCUMBER.

IMPROVED WHITE SPINE CUCUMBER.

LONDON LONG GREEN CUCUMBER.]

BURPEE'S GIANT PERA CUCUMBER.--This wonderful new variety differs in almost every respect from the cucumber as generally grown, and in size and quality far surpasses the ordinary kinds. The vines are very vigorous in growth, with dark green, luxuriant foliage, which enables it to bear large crops of cucumbers of extraordinary size, as they are nearly three inches in diameter and are from 15 to 22 inches in length. The fruit is uniformly round, smooth and straight, the skin being of a pale green and entirely free from spines; when ripe the skin is a russet brown. The green cucumbers are fit to eat at any stage of their growth. The flesh is entirely white, not tinged with green, as in the ordinary kinds, and is crisp, tender and brittle. It has none of the cucumber taste of the older kinds, and is not always relished at first by those who are fond of the strong-flavored varieties, but after becoming accustomed to it for a short time, it is preferred to all others. In its native home it forms one of the staple foods of the inhabitants, being eaten in the natural state without any dressing whatever, in the same manner that we would eat an apple or a pear. It is certainly one of the most remarkable vegetables of recent introduction.

EGG PLANT.

Since the advent of the potato bug in our Eastern States the labor of raising this fine fruit is almost trebled, the bug regarding it as a delicacy superior even to the potato vines, and from its manner of bearing the fruit it is dangerous to apply Paris green or other poisons for their destruction. Where there is time to attend to it I prefer to have the bugs picked off by hand every day, but this is slow work, as we frequently get as many as a pint from two dozen of plants, and they do considerable damage by eating the young shoots and buds, even between such frequent pickings. The best way is to dust with Paris green or other poison, until the plants are of sufficient size to bear fruit, and then to keep the bugs off as thoroughly as possible by hand picking. In preference to Paris green or other strong poisons, I use _Hammond's Slug Shot_, an insecticide that is sold in all seed and implement stores, and which is said not to be injurious to man or beast, though poison is present in the impalpable powder; it is also claimed that it is an excellent fertilizer, as well as being sure death to insects. Having used it three seasons, I have found it very satisfactory for the preservation of all small plants, excepting in one case of young seedlings just coming through the soil, in which case a too heavy application burned them up.

The egg plant is a strong, rank grower and a great lover of rich soil and of heat. The seed should be started in a warm hotbed or greenhouse about the last of March, and the soil should be as rich and light as possible. If the plants grow rapidly, they will be improved by transplanting in the hotbeds, as it will help them to form a good bunch of fibrous roots, so that they will sustain no check when planted out. They should not be set out in the garden until warm weather is assured, and then should be planted in hills enriched as for melons. These hills need not be higher than the surface of the garden, but if strong growth and large fruits are desired, a hole should be scraped out where each plant is to stand, and two or three shovelsful of well-rotted manure or compost put in, and the soil leveled off again before the plant is set. If the ground is dry when the plants are set out, water should be poured in the holes dug to receive them, and the dry soil drawn up around the stems when the plant has been set. The roots of the freshly set plants should not come in contact with the manure, but should have two or three inches of soil through which to seek it as they become established. The fruit should be cut as soon as it is of sufficient size and before the seeds become hard, as it soon loses its fine quality when it begins to ripen. The plants will also continue longer in bearing if this course is pursued, as it takes greatly from the strength of any plant to ripen its seed. When there is danger of frost in the fall all the fruits large enough to use, from the size of an egg up, should be picked off and stored in the cellar, as they will remain fresh and fit for use for over a month at this cool season of the year; by so doing I have frequently enjoyed this fine fruit long after it has disappeared from the tables of my neighbors.

[Illustration: NEW YORK IMPROVED EGG PLANT.]

The hills for the plants should be about two feet apart in the row, and the rows four feet apart. Three dozen plants, which will occupy hardly a third of one of our kitchen garden rows, will furnish an ample supply for a large family. The small early variety matures three or even four weeks before the ordinary kinds, but as they are hardly larger than a good-sized goose egg, it is not worth while to bother with them unless you are especially fond of the fruit and wish to have it as early as possible.

VARIETIES OF EGG PLANT.

EXTRA EARLY DWARF ROUND PURPLE.--This variety is in every respect similar to the New York Purple, excepting in size and time of ripening; the fully developed fruit being about two inches in length and being ready for use a few weeks after planting out in the garden.

NEW YORK IMPROVED LARGE PURPLE.--This is the best and most popular variety. It is of large size, very handsome color and appearance, and the largest in diameter of any variety, yielding large slices for frying. The quality is of the finest.

HORSE RADISH.

This pungent root is a great favorite as a relish in the early spring, and is credited with tonic properties; at any rate it is a very pleasant appetizer at a season when we have been almost without fresh vegetables for several months. It can be raised in almost any soil, though preferring a moist situation, and is most at home where it is constantly moistened or occasionally overflowed by some stream. It is raised from pieces of root, three or four inches in length and from ¼ to ½ inch in diameter. These slips are made from the tails or rootlets cut off in trimming the roots for grating, they should be cut off square at the top and sloping at the bottom, that you may readily know which end goes up when you plant them. The slips should be kept in a box of moist earth, in a cool cellar, after they have been trimmed, until planting time. The slips can be planted with a long trowel; but the best and quickest way is to drive a spade, full depth, into the soil, flatways with the garden line, move it slightly back and forward, to widen the hole, and slip a piece of root down each side of the cut made by the spade, which will make them six or seven inches apart; the spade should then be driven in about one inch back of its previous position and the handle pressed forward, which will pack the dirt solidly against the planted roots, the tops of which should be placed about one inch under the surface. Where it is desired to increase the supply as fast as possible, and where the roots have been used at home, the crowns or tops, with an inch or so of root adhering, can be planted again, but they will not make long, smooth roots, like the slips, but will have a tendency to make several small roots.

HOPS.

At the end of one of the berry rows, or in some corner where they will be out of the way of the plow, there should be a few poles of hops. These are grown from pieces of root, and after being once planted will not need further attention except to be kept clear of weeds and grass, to be supplied with a good topdressing of manure in the fall, and suitable poles to climb upon. These poles should be good strong ones, at least 8 to 10 feet in height. About the last of August or first of September the vines should be cut off near the ground and the poles pulled up, so that the crop may be gathered. There is an old saying that “the September winds should never be allowed to blow on the hops.” The hops should be spread on sheets and placed in some cool, airy garret or loft, to dry. It will take five or six good poles to make a bushel of hops.

LETTUCE.

This is generally known as salad, which is a misnomer, as _salad_ means anything that is served in a green state; it may be onions, tomatoes, cabbage, lettuce, or anything of that kind. By general usage the word salad has been appropriated to the lettuce, as the latter is the plant most frequently grown in this country for salad. But call it whichever you like, it is one of the greatest additions to our tables, and in our kitchen garden it should not be made a side issue of a week or two in the spring, but should be raised in the finest condition possible throughout the season, and by using the hotbeds and cold frames it is possible to have it the whole year round.

To raise head lettuce in perfection the greatest care must be taken to reserve the very best and tightest heads for seed, or if the seed is to be purchased select the hardest-heading varieties. For the earliest planting the seed should be sown in the hotbed and have the same treatment as its associate, the cabbage; the young plants should not be allowed to stand too thickly; they should be at least an inch apart in the seed bed, or be transplanted to that distance when half an inch high. When the cabbage is set out, one

or two lettuce plants may be set between each pair of cabbages in the row, according to the distance the cabbages are apart. There must be space enough between the plants to give the soil a good stirring with the hoe around each plant, as thorough cultivation is essential to the best development of both cabbage and lettuce. A second lot of seed should be planted when the tomatoes and egg plants are sown; these can be set out in the garden as soon as they are large enough to handle. The third sowing should be made in the open garden when the first planting is done, and the young seedlings should be transplanted as soon as the plants are large enough and before they begin to be crowded in the row, as this last sowing will not form heads without it receives the best of care. These three sowings are about all that can be depended upon to make hard heads, unless it can be planted in some rich, shady corner, and carefully nursed with the watering pot.

[Illustration: PERPETUAL LETTUCE.]

About the first or middle of May a sowing should be made of the “Perpetual Lettuce,” and the plants, when large enough, should be transplanted and treated the same as the head lettuce; it will not form tight heads, but produces a fine bunch of broad, yellowish-green leaves, which are very crisp and delicate, not being strong and bitter, as most lettuces are in hot weather. This lettuce will stand from four to six weeks without running to seed, so that if plantings are made about once a month it can be had in perfection throughout the balance of the season. If the head lettuce is more particularly desired, a sowing should be made about the first of August, and another about the fifteenth; the young plants should be transplanted and treated in the same manner for heading as is followed in the spring; the first sowing will not produce heads unless the latter part of August and the first part of September be cool and moist; but you are almost sure to have fine heads from the second sowing. Personally, I prefer the Perpetual, both for its fine qualities and the ease of growing it.

Another way, and the easiest, to have a constant succession of lettuce for the table throughout the season, is to sow the seed thickly in drills and to cut the loose leaves close to the ground when it is three or four inches high; this produces rather narrow leaves, which are very tender and juicy, but which have not the substance of those grown as separate plants or heads, and are not so easily prepared for the table. These sowings can be made every few weeks, and a constant succession of young leaves be had for use throughout the entire season. It should be the object in sowing lettuce to plant small lots frequently, that it may always be had in the best condition.

About the second week in September a sowing of some early hard-heading variety should be made, and a succeeding one about the first of October; from these two sowings the cold frames should be planted, about one-third from the first and two-thirds from the second; the plants should be set about six inches apart each way, which will allow about fifty plants to each sash. When cold weather comes the sash should be put on, and the outsides of the frames banked around with long stable manure. The plants must be treated to plenty of fresh air whenever the weather will permit of it, and on very cold nights the sash should be reinforced with a covering of straw, old mats, or carpet. The lettuce grown in these frames is apt to be infested with the small insect known as the “Green Fly;” to prevent or to get rid of the presence of this pest, tobacco refuse and sweepings from a cigar-maker’s shop should be strewn on the soil under the leaves; this will destroy the fly and act as a fertilizer, but if too much is applied it will spoil the delicate flavor of the lettuce.

If a few very early cabbages are desired, the seed should be sown about the first of October and transplanted with the lettuce into the cold frames; planting them about two inches apart each way; if these are in good condition and the spring favorable, they can be planted out about the 15th of March, and will produce heads one to two weeks earlier than those raised in the hotbeds.

VARIETIES OF LETTUCE.

BURPEE’S HARD-HEAD.--This is the fastest growing and the best heading kind that I have ever grown. With this variety the ordinary gardener is able to grow as fine, large, solid heads as those grown by the professional market gardener. In shape it very much resembles a cabbage, as even the outer leaves tend to curl in over the head, instead of spreading outward, as in most lettuces. In appearance it is quite novel and striking, the edges of the leaves being tinged with a deep brownish-red, while in the centre of its hard heads the leaves are blanched to a beautiful creamy white. In quality it is remarkably tender, rich, juicy, and never bitter.

[Illustration: BURPEE’S HARD-HEAD LETTUCE.]

[Illustration: BURPEE’S TOMHANNOCK LETTUCE.]

BURPEE'S TOMHANNOCK.--This is the finest of all the cutting lettuces, as it is of large size, handsome appearance, and the very choicest quality. It grows very quickly, is soon ready to cut, and stands a long time without running to seed, retaining throughout the season its delicate and delicious flavor. The growth is erect; a fully developed plant is ten to twelve inches in height, and nearly as great in diameter across the top; the outer edges of the leaves curl outward. The outer leaves are shaded with reddish-brown, while the inner leaves are almost white. It is entirely free from any bitter taste throughout the entire summer.

STONEHEAD GOLDEN YELLOW.--This is a new variety, which makes very solid heads, of handsome appearance and the finest quality. Its earliness, large, tight heads and superior quality render it one of the best kinds for forwarding under glass.

[Illustration: GOLDEN STONEHEAD LETTUCE.]

BURPEE'S SILVER BALL.--This, next to the Hard Head, is the best heading variety for general purposes, and where the brown markings in the latter kind are an objection, the gardener will find in this kind all the good qualities that go to make a desirable lettuce. It produces a beautiful head, very firm and solid, with handsomely curled leaves. The head is of a silvery white color, very rich and buttery in flavor, and stands for some time before running to seed. Other excellent varieties of cabbage lettuces are _Philadelphia White Cabbage_, _The Hanson_ and _The Deacon_, while _The Tennis Ball_ is a great favorite with market gardeners for forcing.

[Illustration: BURPEE'S SILVER BALL LETTUCE.]

OKRA.

This plant, like the carrot, is too little grown, as its green pods impart a fine flavor and consistency to soups and mixed stews; besides being very palatable when stewed and served as is a dish of asparagus; the pods can also be dried for winter use. The seeds should be planted in drills, and if the dwarf variety be used, which I think is preferable, as it produces an abundance of pods and does not take up nearly so much room, the plants may be allowed to stand about one and a half feet apart in the row, the rows being three feet apart, though a quarter or half a row in the kitchen garden, as here described, will furnish an ample supply, both for use and drying. For either purpose, they should be cut before the pods attain their full size or they will be hard and woody. For drying, the best way is to string them on a fine wire or thread and suspend them to the rafters of a cool loft or garret until wanted for use. The culture of this vegetable is very simple, as the seeds are planted in drills about two inches deep, and the after treatment is the same as for corn.

[Illustration: OKRA.]

ONIONS.

In raising onions in quantities the practice of late years has been to grow the crop from seed in one season, instead of the method formerly almost universally practiced in this section, of raising and keeping over sets to form the next year's crop. This latter method is now only practiced to save labor in small gardens and to bring a few onions in for use early in the season.

To raise a satisfactory crop the ground must be free from weed seeds; it must be made as rich as possible and have constant cultivation from the time the seedlings break through the ground until the bulbs begin to ripen. The soil must be plowed, harrowed and raked, until it is in the finest possible condition to receive the seed, and it is important to select a plot for this purpose that has been kept free from weeds the preceding season. Root crops are the best to precede onions, as they not only leave the ground free from litter, but also, if they have been properly cultivated, leave the soil in fine tilth.

In our kitchen garden I would sow the seed in drills, twelve to fourteen inches apart, and cultivate with the wheel hoe; in field culture, or raised more extensively in the garden, plant in rows as closely as they can be worked with the cultivator, which, if it is provided with very narrow-bladed teeth, can be run through any rows where the horse can walk. For the kitchen garden, make the surface fine with a sharp steel rake, and if no drill is at hand, take a rake handle or blunt stick, and, drawing it along the garden line, scratch a drill about an inch deep. Sow the seed thinly, say an inch apart, but if there is reason to doubt the freshness of the seed, sow it thicker, so that a good stand may be assured. When the onions are an inch high, they should have their first working. Follow the wheel hoe or cultivator with a narrow-bladed hoe, not wider than an inch and a half at the cutting part of the blade; it must be sharp and lightly handled, just loosening the ground and cutting off any stray weeds. If there are no weeds the soil can be quickly loosened with a sharp steel rake. They should be worked every eight or ten days from this point until they begin to ripen; if it is neglected for longer periods than these, the gardener will rue it in days of back-breaking labor on hands and knees. When the

young onions have made leaves two or three inches in height, they should be thinned out to from four to six inches apart in the rows, according to the size of the bulb made by the particular variety planted. The seed for onions grown in this way should be sown as early in the spring as the soil can be gotten into the proper fine condition, so that they may make as strong a growth as possible before the hot summer weather ripens them off. As they begin to ripen, all those with thick necks should be pulled and used upon the table, as they will not ripen properly, and if put away with the good bulbs will start all to rotting. There is a theory common with old gardeners that, by bending the tops over when they begin to ripen, the bulbs will be increased in size and will ripen more quickly; personally, I have tried it frequently, and have never been able to observe any difference in those bent and the ones left to ripen in the natural way. As soon as the bulbs are well matured, take them up at once, as a few rainy days might start them to growing again if left in the ground; pull off all the tops and roots which adhere to the dry bulbs and spread them thinly on the barn floor or on the floor of a cool loft. When it becomes too cold to let them remain longer in this position without danger of freezing, I put them in peach baskets, the stripped sides of which allow a free circulation of air, and store them in a cool, well-ventilated cellar, where we try to keep the temperature just above freezing by admitting air whenever possible, as it takes but very little warmth to start them to growing, and then they soon become unfit for use. If the gardener saves his own seed, the finest and best-shaped onions should be laid aside for planting out in the spring, for this purpose.

Where the crop is raised from sets it is not necessary, though quite desirable, to have the soil made as fine as for the seed bed. As the small onions are set in, planting at the proper distances apart, almost all the cultivation can be done with the narrow onion hoe, and if it is regularly attended to at proper intervals no hand work is necessary. The onion is a hardy bulb, and the sets can be planted as soon in the spring as the ground can be gotten into proper condition; this makes an important feature in the earliness of the crop, as the sets have several weeks the start over the onions raised from seed. For the very earliest onions, or those used when the bulb and neck are about of equal thickness early in the spring, and which go by the name of scallions, the sets are planted in October and allowed to remain in the ground all winter, so that they are ready for use almost as soon as the spring opens, two weeks' growth sufficing to bring them to a proper size. Where the main garden crop of these fragrant bulbs is raised from seed, enough sets should be planted to make an early supply for the table; if no sets are at hand in the fall, to plant for the spring crop of scallions, they could be grown by sowing the seed about a month earlier than you would plant the sets for the same purpose.

In sowing seeds for sets the same directions apply as given for the crop of bulbs, excepting that the seed is sown much more thickly, so that the bulbs will touch each other and stand two or three wide in the row. If they do not seem to be making the proper growth as the season advances, they should be thinned to the proper extent to enable them to grow to the right size, one-half inch in diameter, though my own trouble is that they usually grow too large; to remedy this when they are nearly the proper size I allow them to become choked with grass and weeds, which checks their growth, but when this is done they must be watched that this mass of stuff does not rot them off when ripe. I think a better way would be to go along the row with a straight-edged hoe or spade and cut off some of the roots. The main object in having the sets of this small size is that they shall not run to seed when planted out in the spring. Any sets which exceed three-quarters of an inch in diameter should be used for pickling or cooking. When the sets begin to ripen it will sometimes facilitate the process to bend all the green tops over close to the bulbs, as it helps to dry and shrivel the tops more quickly. When thoroughly ripe they should be gathered at once, the tops and roots pulled off, and should be spread out and stored for winter in the same manner described for the large onions. Any of the sets that persist in growing and not drying properly, should be thrown out, or they will spoil the whole crop. If a suitable cellar or loft is not available for storing the bulbs where they will be sure not to start into growth, they may be wintered on the barn or loft floor, covering with hay as the cold weather advances. The hay should be only two inches thick at first, but should be increased to one foot in thickness as the season advances, and in the spring should be removed by the same graded process.

VARIETIES OF ONIONS.

YELLOW GLOBE DANVERS.--This is a splendid variety, and is the most popular and profitable kind to grow for market. It is similar to the Yellow Danvers as ordinarily grown, excepting in shape, which is much finer, in my opinion. No one can fail to be pleased with this fine variety when well grown. It is quite early, and is one of the very best keeping kinds.

[Illustration: YELLOW GLOBE DANVERS ONION.]

LARGE RED WETHERSFIELD.--A strong grower and produces immense crops of large, fine bulbs. It is rather flat in form, deep purplish red on the outside and a much lighter shade inside. It has a strong flavor, and is very solid, making an excellent keeping and shipping sort.

[Illustration: RED WETHERSFIELD

COPYRIGHTED 1887.

W. ATLEE. BURPEE & CO. PHILA

LARGE RED WETHERSFIELD ONION.]

WHITE GLOBE.--One of the handsomest onions grown, beautiful in shape and color, having a clear, white skin; the flesh is fine grained, of mild flavor, and the bulbs are of good keeping quality.

WHITE SILVERSKIN, OR WHITE PORTUGAL.--This is an old and favorite variety, being very desirable for planting in the family garden; the flavor is the mildest of the American varieties; the small onions are very fine for pickling. I think this variety should be marketed as early as possible, as with me it is not a good keeper.[6]

[Illustration: WHITE SILVERSKIN

SILVERSKIN, OR WHITE PORTUGAL ONION.]

ITALIAN VARIETIES OF ONIONS.

GIANT RED ROCCA.--These onions are of large size, handsome appearance and mild, delicate flavor. In this variety we have an onion which attains a weight of from one to two pounds under ordinarily good culture, and of most handsome shape and appearance, the outer skin being always bright red, while the flesh is white, mild and pleasant.

EARLIEST WHITE QUEEN.--This variety does not grow to the large size of the other Italian kinds, more resembling our American Silverskin in size and appearance, but has the great advantage over the latter variety (which takes two seasons to attain the same size), of remarkably quick growth, while the flavor is equally, if not more, delicate. The bulbs are flat, pure white and about two inches in diameter. It is the finest variety for pickling grown. Sown in February, they will produce onions early in the summer, while if sown in July, they will be ready to harvest in the fall, and will then keep in splendid condition throughout the winter.

[Illustration: NEW GIANT RED ROCCA ONION

GIANT RED ROCCA ONION.]

[Illustration: WHITE QUEEN ONION.]

GIANT YELLOW ROCCA.--This variety is similar to the Giant Red Rocca described above, except in color, which is a clear golden yellow. It is this variety which is the real "_Spanish Onion_," so generally sold at the fruit stands in the cities.

BURPEE'S MAMMOTH SILVER KING.--This I believe to be the handsomest variety of onion grown, as I think the white-skinned varieties the most attractive. The bulbs are slightly flattened, but are very thick through, averaging five to six inches in diameter, and have been grown to the enormous weight of over four pounds to the single bulb, while two-pound bulbs are frequently produced under fair culture. The skin is a beautiful silvery white; the flesh is even whiter, while the flavor is very mild and pleasant, the Italians eating them as we do apples.

PARSLEY.

This should be grown by every gardener on account of its usefulness, both for seasoning and garnishing. As it seeds in the second season, fresh plantings should be made every spring. The seed, being very slow to germinate, should be soaked in tepid water for twenty-four hours before planting. The best way is to sow in the hotbed or cold frame and transplant to the garden, but it can be sown in drills where wanted and thinned out to the proper distance apart. I always try to have a bed of it near the kitchen door, as it saves much running; if such a bed cannot be conveniently placed, some should be cut and brought in with the other vegetables, as it will keep fresh some days if kept in cold water. In the fall some of the best roots should be taken up and planted in the cold frame, or put in pots and boxes in the sunny windows of the house, for a winter supply. The leaves and tops from trimming the celery are also very fine for flavoring.

[Illustration: EXTRA CURLED DWARF PARSLEY.]

The EXTRA CURLED DWARF is so much finer and handsomer than the other kinds that it should be the only one grown.

PARSNIPS.

This is a winter vegetable, needing hard freezing to refine and bring out its best quality; the roots should be left to stand where grown until they can be dug in the spring or through the winter as wanted, though some may be dug and stored in heaps for use when the ground is frozen too solidly to admit of digging them. If there is more than are wanted for table use, there should be no delay in getting them dug and marketed as early in the spring as possible, for when they begin to sprout and grow, they very soon become woody and unfit to eat. A row should be sown in the garden at the same time as the onions, beets, etc., are planted. It is best to sow the seed quite thickly; by thickly I mean one seed every inch or so; when the young plants are about three inches high they should be thinned out to six inches apart in the row, care being taken to leave only one plant in a place, as, if two are left, they will spoil the symmetrical shape of the roots by growing against each other. In planting the seed I always try to run it in between two rows of beets, onions, lettuce, or other early crop, thus working it with the wheel hoe while small, and when the other crops have been taken off there is room to work it with the cultivator, which is run as close to the rows and as deeply as possible, so that the roots may attain the largest size. In digging the roots when the ground is frozen hard and is impenetrable to the spade, I use a long iron post digger with a steel blade.

[Illustration: IMPROVED GUERNSEY PARSNIP.]

VARIETIES OF PARSNIPS.

For the last three seasons I have grown the IMPROVED GUERNSEY, and have found it so much superior in size and quality to the Long Smooth, as to be above comparison. The roots are smooth, fine shaped, and free from small roots, while the quality is very superior.

PEAS.

The first planting should be made in the spring, as soon as the ground can be prepared. It is my practice to sow three varieties at the first planting, and two varieties at each subsequent one, kinds being sown which will mature in succession, one being ready to pick about the time the preceding one is past. The same result may be obtained by making plantings of the same sort a week apart. I think my way the easier, and besides, relish the variety. A drill of fifty feet would probably be sufficient for an ordinary family to have in bearing, but as my own family is large and very fond of this vegetable, and insist upon having them upon the table every day in the season when it is possible to grow them, I find a full row across the garden none too many to have in bearing at one time.

For several years past I have given up raising the tall growing peas requiring brush or sticks for their support, as it is not easy to procure sufficient brush for a garden of this size, unless you have a convenient woods upon which to draw, and even then it takes a great deal of labor to get the brush and stick the peas; while it takes more than twice as long to clear the ground for the succeeding crop, and the rows must be planted at a greater distance apart, to admit of cultivation.

The quality of the dwarf kinds is fully as good as of the tall growing ones, and in many kinds the crop borne is fully as prolific; the only strong point that I know of in favor of the brushed peas, is that the pickers do not growl half so much at picking them as they do over the lower growing ones, and that some of the varieties can be had later in the summer, as their height serves to shade the ground between the rows and thus keeps it cool. As for the growls of the picker, the short vines admit of no loafing place, and no true gardener or lover of his craft ever seems to be aware that he has such a thing as a spine (except on his cucumbers) till he tries to straighten up at the end of the day’s work.

For sowing the seed, plow a drill as deeply as possible with the hand plow; sow the seed thickly, say a quart to 200 feet of drill, and cover by plowing the dirt back again; when the hand-plow is not among the assortment of tools, scrape a drill three inches deep and as broad as the blade of the hoe, scatter the seed the whole breadth of the drill, using about one-third more seed than above directed, and then press them into the bottom of the drill with the sole of the boot, covering the fine dirt in afterward with a steel rake; this takes longer to do, but is a much better way to plant them when the time can be spared; the row being broader it gives the plants more room, and the seed being planted more deeply will better withstand the hot weather. For the very earliest planting the seed should only be covered about an inch deep, and more soil can be drawn around them when well started. The successive plantings of peas should be kept up until the middle of June; those planted later than this will mildew, and not fill out the pods, unless in a cool and shady situation. The plantings should be resumed about the first week in August, and three successive

plantings, about ten days apart, should be made. The vines and pods of these peas will most likely mildew, but the peas that you will get in the cool days of the fall will be the finest in quality, of the whole season. In selecting the sorts to plant, the wrinkled varieties will be found of better quality than the smooth kinds, the latter requiring to be picked while quite young, as they become hard, while the wrinkled ones remain longer in good condition.

VARIETIES OF PEAS.

BURPEE'S EXTRA EARLY.--This is a remarkably early selection of the well-known Philadelphia Early. It is the first variety to ripen, ripens nearly all its pods at one time, and is very sweet and tender when cooked; the vines grow about two feet in height, but can easily be supported by driving stakes every few feet and confining the vines with twine running from one stake to another.[7]

[Illustration: BURPEE'S EXTRA EARLY PEA.]

AMERICAN WONDER.--This little fellow is really a _wonder_, as it grows only eight to ten inches in height and is literally covered with pods. It is remarkably early, ripening in from thirty-five to forty days, and in succulent sweetness cannot be surpassed.

[Illustration: AMERICAN WONDER PEAS.]

EXTRA EARLY PREMIUM GEM.--This variety is about ten days later than the American Wonder, and grows from twelve to fourteen inches in height. The peas are remarkably fine in quality, and I have planted it for several years as my main variety.

PRIDE OF THE MARKET.--A new pea that I have grown the past two seasons, and find of very superior merit. The price of the seed has been too high to admit of extensive planting, but with these three dwarf kinds, the only ones planted for the table this last season, I can say that I have never been better supplied, or with finer peas. This variety grows about a foot and a half in height and bears a very heavy crop of pods, which latter and the peas that they contain are of unusual size and substance.[8]

[Illustration: LAXTON'S EVOLUTION PEA.]

LAXTON'S EVOLUTION.--This variety is a novelty in the way of peas; in the other varieties the object having been of late years to have the pods all mature as nearly as possible at the same time; this object has been sought for the benefit of the market gardeners, while in this new variety we have a kind which will, from its everbearing habits, be a great boon to the family gardener. The vines grow about three feet high, and bear continuously, for a space of nearly three months, an abundance of handsome, large pods, each of which contains eight to ten wrinkled peas, the pods being borne in clusters of two, which facilitates the picking. Like all wrinkled varieties, the quality of this remarkable pea is most excellent.

CHAMPION OF ENGLAND.--This is a large growing late sort, and is very productive, with peas of delicious flavor. The vines grow to four or five feet in height, and this past summer I ate them in perfection fully a month after the other varieties had disappeared from the table.[9]

COPYRIGHT, 1887, By W. ATLEE BURPEE.

BURPEE'S QUANTITY.]

PEPPERS.

The seed should be sown about the middle of March, in the hotbed, if wanted for summer use, and as soon as the nights are warm they should be planted out. They can be sown in the open ground if the fruit is not wanted for use before fall. As they are used in preparing various kinds of pickles, etc., it would probably be the better plan to plant some at both times. When about six inches high, they should be transplanted to the rows where they are to fruit, and should be set about two feet apart in the row. Where room is scarce, I usually set two pepper plants between each hill of cantaloupes, as they grow well above the vines and are not at all in the way, while having the ground shaded from the hot sun by the vines of the melons, the surface being kept cool and moist by their broad leaves, is of great advantage to the peppers. In choosing varieties, those kinds having the mildest flavor and handsomest appearance should be selected.

VARIETIES OF PEPPERS.

BURPEE'S RUBY KING.--This variety produces the handsomest, and at the same time the largest and mildest peppers that I have ever grown; one specimen this season being six inches long and over ten inches in round circumference. When ripe the fruit is a beautiful, bright, ruby-red color, and the flavor is mild and pleasant, being much milder than in any other variety of red pepper.

[Illustration: BURPEE'^S RUBY KING.]

BURPEE'S GOLDEN UPRIGHT.--In this variety the fruit grows in a different manner from any other large pepper that I have ever seen; it grows upright on the fruit stems, instead of pendulous. The fruits are large and handsome, being about four to five inches in length, and are of rich golden yellow tinged with red. In taste it is as mild as the Ruby King--the two making a very fine contrast when used together.

[Illustration: BURPEE'S GOLDEN UPRIGHT PEPPER.]

BULL NOSE AND GOLDEN DAWN are the finest of the older kinds, but do not compare with the two above given, either for size or mildness of flavor.

RED CLUSTER.--This is one of the finest varieties that I have ever grown; it is low and bushy in growth, and is covered with a profusion of thin, round peppers, about three inches in length and one-quarter inch in diameter at the base, tapering to a long, sharp point. When ripe, the fruit is a brilliant coral red, and a plant covered with fruit looks like some brilliant-foliaged plant that has escaped from the flower garden. It is very hot and pungent in flavor, and an idea of the productiveness can be had from the fact that over twelve hundred were counted on a single plant this last summer.[10]

PUMPKINS.

These take up so much room that they properly belong in the corn field, or in a patch of their own, in one of the cultivated fields. If there is no place for them outside the kitchen garden, and they can be kept far enough away from the squashes and cantaloupes, they can be planted about every twenty feet, in every fourth row of potatoes or sweet corn. They should not be planted until the corn or potatoes have grown three or four inches high, or they will be in the way of cultivating these crops. If one row of the corn were left out, and a row of pumpkins planted, it would probably be the most satisfactory way to grow them, as the tall growing corn, of which there should be at least five rows between them and any other vines, would prevent the pollen from mixing, and as the hills need only be four or five feet apart, a great many could be raised in a row. The pumpkins must all be gathered in and stored before any heavy frosts, as it will spoil and start them to rotting.

[Illustration: SMALL SUGAR PUMPKIN.]

[Illustration: NEW GOLDEN MARROW PUMPKIN.]

VARIETIES OF PUMPKINS.

SMALL SUGAR.--This is very handsome and prolific, of small size, the pumpkins averaging about ten inches in diameter; the skin is a deep orange yellow. It is very fine grained in flesh, sweet in taste, and an excellent keeper.

GOLDEN MARROW.--Of round shape, slightly ribbed and flattened at the ends; the skin is a rich golden orange color; the flesh is of extra quality, and very soft and tender when cooked. It is a splendid keeper, vigorous grower, and keeps well throughout the winter.[11]

RADISHES.

These should be sown as soon as the ground can be worked in the spring, and successive sowings should be made every two or three weeks, as recommended with peas, lettuce, etc. Do not sow too many at one time, but sow frequently, that they may be had fresh and crisp; they soon become either hollow, or hard and woody, if allowed to stand long after they are of sufficient size for use. Where there is glass enough to spare, it is an excellent plan to sow two or three rows in the hotbed at each planting of seeds, which will furnish them for use several weeks before they can be had from the garden.

There is a general impression that radishes do not do well except in very light soil, while my experience is that it is mainly a matter of manure and cultivation, and that good radishes can be raised early in the season on the heaviest of soils, though later in the season they will not succeed unless the soil be favorable. Where "Night Soil" can be obtained and composted with ashes, it will

make the finest kind of manure for the radish bed; but it should be applied with judgment, as it will burn up any crop if applied too heavily. This manure can hardly be so readily applied in a special location in the garden worked by horse power, and I strongly disapprove of making “beds” in such a garden; it should be kept as level as possible, that all the cultivation may be done with the wheel and horse hoes; while “beds” mean lots of slow hand work, and hard beaten ground in the paths and edges, that are perpetual sources of weeds; while in the level garden the location of rows and crops can be continually shifted, every portion of the ground being used, and none escaping cultivation.

For the earliest plantings, the small, very early kinds should be used, and these will grow the finest radishes of the season, fresh, crisp, and slightly pungent. For summer use, the large summer kinds, of very mild flavor, should be selected. These latter should be planted from the first of June until the first of August, after which I begin to sow the small early kinds again, having found that I can grow them as fine and palatable as in the spring. In sowing these in the kitchen garden I sow a part of a row at a time, in the portion worked with the wheel hoe, where the rows are about one foot apart; the seed is sown thinly in the drills, and if it comes up too thickly, should be thinned out to one inch apart for the small kinds and two inches for the larger ones. The seed should be sown from one-half inch to one inch in depth, according as it is early or late in the season or in heavy or light soils. The radishes should be pulled early in the morning and kept in fresh water in a cool cellar until used, so as to have them fresh, brittle and crisp. The large winter varieties are not much raised, except by the Germans, being rather too pungent for the American taste.[12] The seed is generally mixed with the turnip seed and broad-casted or drilled in together, but if I were planting them, I would think it much better to sow them in drills and cultivate separately.

VARIETIES OF RADISHES.

BURPEE’S EARLIEST (_Scarlet Button_).--I have grown this new radish for two seasons and consider it the earliest and finest radish that I have ever grown. It is _the_ earliest, about one inch in diameter, handsome, crisp and brittle. The color is the deepest scarlet. It has very small leaves, and a great many can be grown in a small space, rendering it very valuable for forcing. Last winter I sowed seed between the rose bushes in my forcing houses and kept my table supplied, and had large quantities to sell.

[Illustration: BURPEE’S EARLIEST (SCARLET BUTTON) RADISHES.

Natural size, when ready for use.]

EARLY LONG SCARLET SHORT TOP.--This is a fine selection of the long, slender scarlet radishes so generally seen in the spring, and is preferred by some to the round or turnip radishes. It is very early, tender, crisp and fine flavored; the roots averaging half an inch in diameter at the top and tapering from that throughout their length of four or five inches.

EARLIEST CARMINE, OLIVE-SHAPED.--A very early radish, of a rich carmine color, and while not so early as Burpee’s Earliest, attains fully twice the size; the roots are of an even, regular olive shape and very fine quality. It is an excellent radish for forcing, on account of its size and appearance and the small growth of top which it makes, enabling many to be grown in a small space.[13]

[Illustration: LONG SCARLET RADISH.]

[Illustration: EARLIEST CARMINE, OLIVE RADISH.]

SUMMER VARIETIES OF RADISHES.

GOLDEN GLOBE.--This variety is of very quick growth and fine quality, being ready for use in from four to six weeks after sowing the seed. In shape it is almost entirely round, the color quite bright, and the quality very sweet and crisp.

GIANT WHITE STUTTGART produces very large roots, frequently reaching the size of an ordinary turnip; it is very quick growing and resists the heat of summer well, being firm and brittle until it runs to seed. The skin and flesh are pure white, a good guarantee of its mild flavor.

[Illustration: GOLDEN GLOBE RADISH.]

[Illustration: GIANT WHITE STUTTGART RADISH.]

[Illustration:

LONG WHITE VIENNA, OR LADY FINGER RADISH.]

LONG WHITE VIENNA.--This is a very fine long, white radish, both skin and flesh being pure white; it is crisp and brittle and rapid in growth, and to my mind of a much more attractive shape than the large globe radishes, which, unless pulled young, are too large for any but the confirmed lover of radishes.

LARGE WHITE GLOBE.--A very large, round, summer turnip radish, with pure white skin and flesh, which is very crisp and brittle. It grows quickly and withstands heat well. It is similar to the Golden Globe, except in color.[14]

[Illustration: LARGE WHITE GLOBE RADISH.]

[Illustration: CALIFORNIA MAMMOTH.]

WINTER VARIETIES.

CALIFORNIA MAMMOTH WHITE.--This is the largest of all radishes, the roots growing eight to ten inches long and two to three inches in diameter, while the flesh is solid, snow white and of excellent flavor.

CHINESE ROSE.--This is a bright, rose-colored variety, of very attractive appearance; it is of excellent quality, a good keeper, and one of the best varieties for winter use.

POTATOES.

A small planting, say two or three rows, of these should be made as early as possible in the spring, the amount planted depending on how soon they will be followed by the main crop. These may be planted in the furrow when the ground is plowed, but I prefer to plant the earliest ones in furrows struck out about three inches deep, after the ground has been thoroughly prepared, as they will come up more quickly. The rows should be dressed with phosphate, to give them a quick growing start, and the pieces of tuber placed about one foot apart; the ground may be run over with a sharp spike harrow when the potatoes are just coming through, or left a little longer and then worked with the cultivator. The soil must be kept well worked, and as close to the roots as it is possible to run. The bugs must be watched for and destroyed as soon as they appear, either by dusting with Paris green mixed with plaster, or with other insect poisons, or by picking them off and destroying them by hand, which is the easier way when the patch is small and potato plants are young. If these early bugs are destroyed before they can lay their eggs, the work of protecting the summer crop will be greatly lessened. Where the main crop of potatoes is to be raised in the garden, they should be planted about the first day of May, or the middle of April, that they may be harvested by the middle or last of August, and the ground used for a crop of turnips, peas, or other second-crop vegetables. As soon as the vines begin to die, and the skin of the potatoes is well set, so that it will not rub off with the fingers, the tubers should be dug or plowed up and stored, not only that the ground may be used again, but because, if they are left in the ground, they will either start to grow again or begin to rot. When dug, I pile them in small heaps of twenty bushels or so on the barn floor, dusting each pile as it is made with dry, air-slacked lime, about a quart to a heap; this helps to dry and preserve them, and prevents any tendency to rot. The barn doors are left open through the day, for a few days, and the potatoes dry gradually, until time for storing them, when it comes cold, though where there is a cool vegetable cellar it will save time to store them at once, and, of course, at this time of the year the ventilators of the cellar should be wide open. Where the cellar is too warm and the potatoes start to sprout, it is said that it may be prevented by turning them frequently, but I have never had an opportunity to try it. The first planting should be made of some very early ripening varieties, while the main crop should be of a kind selected for good size, heavy cropping, and the best cooking qualities.

SWEET POTATOES.

Like some other vegetables, these are generally supposed to require special soil and situation to do well, but with plenty of manure and good cultivation they can be raised of fine size and quality in any garden. As described in the chapter on hotbeds, the old potatoes are planted in a warm bed, about the first of April, and when the ground is prepared, these are taken up and the sprouts broken off close to the potato. The potatoes should be buried two or three inches deep in the bed, which will give each shoot a bunch of fine roots when it is broken off. When the nights are warm, and the trees well out in leaf, plow a double furrow where the row of sweet potatoes is to be; that is, run the plow each way in the same furrow; then fill in two or three inches of fine manure, and plow the furrows back again, forming a ridge over the manure. In the centre of this ridge plant the sets about one foot apart; they must be kept well cultivated, and the running vines must not be allowed to strike root into the soil, or they will form lots of small potatoes, and none large enough for use; some gardeners keep the vines coiled round the central plant, but the easier way is to throw the vines from two rows together, then cultivate the side left bare, and throw them back again, cultivating the other side; after

the first time they need not be moved but once for each cultivation, as the blank side can be cultivated and the vines thrown over on it, leaving the other side free, which can be cultivated first the next time it is done, and the vines thrown back. Throwing the vines over can be done very quickly by running a rake handle or long light pole under them, and throwing its whole length of them over at once: they can be dug as soon as large enough for use, by scraping the dirt away from the side of the hill, the potatoes pulled off, and the vines left to form more. The whole crop should be dug as soon as the vines are blackened by the first frost, and spread out in a cool dry place, where there will be no danger of their freezing. On account of the vines taking so much room, the rows should be at least five feet apart.

SAGE.

A dozen roots or more of this herb should be planted in some part of the garden where it will not be disturbed by the plow, or if this cannot be done readily, the roots can be taken up when the plowing is done, divided and reset, which would probably raise a larger and finer crop of leaves than allowing them to stand in the same place year after year. The crop should be cut off a few inches above the ground, as soon as it has made its growth and before it begins to bloom. The shoots will again start to grow, and two or three crops can be cut in a season; the cut tops can be tied in bunches and hung to the rafters, or spread thinly on the floor of a cool loft or garret.

SPINACH.

This is a quick-growing green, and very hardy, making it valuable for early spring and late fall growing. It cannot be raised during summer, on account of its running immediately to seed without making many leaves. It can be sown as soon as the ground can be worked in the spring, and will be ready for use in a few weeks; about three sowings may be made, two weeks apart, or more, if the season is longer, though it will hardly be good if planted after the middle of May. The whole plant is cut off even with the ground, at any time before it starts to run to seed, the leaves and stems being used as boiled greens. Large sowings should be made in October, of the hardy variety, as it can be cut throughout the winter; a later sowing may be made the first of November, and lightly covered with litter when the ground has been frozen hard; this covering should be raked off early in the spring, and it will complete its growth before the first spring planting is ready for use.

VARIETIES OF SPINACH.

NEW THICK-LEAVED ROUND.--This variety produces large, thick, dark green leaves, somewhat crumpled. It possesses the valuable quality of standing for some time after attaining its growth, before running to seed.

[Illustration: NEW LONG-STANDING SPINACH.]

THE NORFOLK SAVOY LEAVED.--The leaves of this kind are wrinkled like a Savoy cabbage. It makes a large bunch of succulent leaves, producing more weight of leaves than any other variety, and is more hardy than any of the other kinds.

NEW LONG STANDING.--This is one of the best varieties for spring sowing, as it stands longer than any other before running to seed. The leaves are thick, fleshy and crumpled like the Norfolk Savoy Leaved.

SQUASHES.

Hills should be made for the culture of these, in the same manner and at the same time as described for cucumbers, cantaloupes, etc. These hills should be at some distance from the vines above mentioned, as there is danger of the pollen mixing and spoiling the melons, etc. There are some localities where the winter squashes do not do well or are difficult of cultivation; but the small summer squashes are of easy culture in any locality, though of finer quality on a warm sunny slope than elsewhere. The only trouble in growing them is to protect them from the ravages of the Striped Squash Bug while young, for which purpose I use slug shot, dusted on the leaves early in the morning, while the dew is still on them.

The vines should be allowed plenty of room to run, at least four feet on every side. The vines soon cover the ground and prevent using the cultivator; but the large leaves so shade the soil that few weeds grow, and where they rear their heads above the vines they can be cut out with hand hoes or pulled out after a rain, by hand.

As we can hardly use the product of more than a dozen hills, I divide the long row across the garden into three parts, planting the squashes at one end, watermelons in the centre, while the other end is occupied by cucumbers, which prevents any mixing of

pollen, and gives a sufficient quantity of each fruit without disturbing the symmetry of the garden. In gathering the squashes for table use, care must be taken that they are not too old, or they will be tough and stringy when cooked; the easiest way to judge them is to try them with the nail or small stick; if it does not cut the skin freely and easily they are too old; no push should be required to make the cut. This is also a good test when in doubt about the proper condition of sweet corn, and should be applied to grains near the base of the ear. No old squashes should be allowed to remain on the vines of the summer varieties, for if they are allowed to ripen, the vine, having fulfilled its natural purpose, will dry up and die, while if the fruits are picked off, it will continue to grow and produce fruit.

The winter squashes are raised in the same manner, but are more difficult to start, as the young plants are subject to a borer which eats them off under ground. Plenty of seed should be sown in each hill, and as soon as you see a plant wilting or cut off, dig around its roots with your fingers or a stick until you find and kill the borer, otherwise, he will continue his labors on the other plants in the hill. The plants should also have careful watching and dusting, to preserve them from the usual insects that prey on young vines. When the plants are about one foot in length they should be thinned out to two or three in a hill, though the danger from borers is hardly passed yet, but to allow them to stand too thickly after attaining this size would stunt them and lessen the crop. The squashes should be gathered before there is any hard frost and stored in a cool, well-aired cellar. Some of the winter varieties are equally good for summer use before they become too old and hard; if these are planted, the one planting will furnish fruit for both seasons.

SUMMER VARIETIES OF SQUASHES.

EARLY WHITE BUSH, OR PATTY-PAN.--This is the best known and most generally planted of the early squashes; when young the quality is very fine, the flesh is fine grained and of delicate flavor. It is a bush variety and the vine does not “run.”

[Illustration: EARLY WHITE BUSH SQUASH.]

[Illustration: GOLDEN SUMMER CROOKNECK SQUASH.]

GOLDEN SUMMER CROOKNECK.--A small crook-necked summer squash, the skin of which is a bright yellow color and is covered with warty excrescences. It is early, productive and of excellent flavor.

WHITE PINEAPPLE, OR WHITE TURBAN.--This variety produces a very handsome fruit, though of peculiar shape, as will be seen from the accompanying illustration. The blossom end of the squash is smooth and round, while from the stem end start ribs or ears, which attain their largest breadth and end near the middle of the squash; these ears usually grow in pairs. This variety is of excellent quality, and can be used at any stage of its growth, and the full-grown fruits can be preserved for early winter use. The skin and flesh are both of a pure creamy white tint; the flesh being very thick, while the seed cavity is quite small. The flesh is fine grained and of the best quality, possessing a rich cocoanut flavor.

[Illustration: WHITE PINEAPPLE SQUASH.]

[Illustration: ESSEX HYBRID SQUASH.]

WINTER VARIETIES OF SQUASHES.

ESSEX HYBRID.--A very productive squash of the finest quality and an excellent keeper, specimens having been kept until June, as sound and good as when gathered. It is one of the richest flavored, finest grained and sweetest of all squashes, while at the same time it is one of the largest and most productive, growing close together on the vines and averaging from eight to twelve pounds in weight. It is of early, quick growth, and can be raised very successfully as a second crop, following early potatoes, peas, etc.

[Illustration: HUBBARD SQUASH.]

HUBBARD.--This is a standard and well-known winter squash, and is of most excellent quality for winter use, but is not so well adapted to all soils and localities as the preceding varieties, nor of such easy culture.

TOMATOES.

These rank with the standard vegetables, such as corn, potatoes, etc., and yet it is not many years since they were grown in flower gardens only, the brilliant color of their fruit being then considered quite a pleasing novelty. Now, by the introduction of the canning industry, there is not a day in the year when they are absent from our table. Their culture is of the simplest, being largely a matter of soil and manure and good early plants, to be set out as soon as the weather will permit in the spring. The seed is sown in hotbeds, from the middle of March to the middle of April; if possible, they should be transplanted, when about two inches high, to another sash, where they may stand three or four inches apart. When there is not room for this, the seed should be sown thinly in drills four inches apart, and when well started, should be thinned out to two inches apart in the row. The hotbeds should be given plenty of air on warm days that the plants may be stocky and thrifty when planting-time comes. They should not be set out until the temperature is over 60° at night, or until the oak trees are well out in leaf. They should have plenty of room, at least three feet in the row and four feet between the rows, and for an ordinary family at least four rows should be planted. Two rows should be of the earliest and two with plants sown a month later, for in some varieties there is a tendency to die off after raising one crop, though constant picking as fast as they ripen, and not allowing surplus ones to remain on the vines, will greatly prolong the bearing period; so much so, that in most years I make but one planting. The earliest hotbed plants will begin to ripen fruit the last week in July or the first in August, while, if you make a hill, as for corn, about May 10th, and put in a dozen or so seed where you want the plant to stand, pulling all out but the strongest one when they get a good start, you can have this second lot in bearing about the last of August, without the use of glass or the labor of transplanting.

The young plants must be thoroughly cultivated and hoed; when hoeing, the dirt should be loosened right up to the plant, and when it has been worked loose and made fine should be drawn up to the stem, two or three inches in height. It frequently happens, when the season is late, that the plants have grown a foot, or even two feet, in height or length. This is no disadvantage, but rather a help, if treated in the following manner: A gutter two or three inches in depth and nearly the length of the plant, is scraped under the planting line with the hoe, and the plants laid lengthwise in this and covered over, all but about five or six inches of the top, which is bent straight upward and afterward treated as though it were a plant of that size; the long stem underground immediately forms roots and assists in feeding the growth of the plant.

The ground should be well manured, but if the soil is light it can be overdone, as the plant will run too much to vine and be late in producing fruit. I have found that, though there is a general impression that tomatoes do best on a light, sandy soil, the best tomatoes I have ever raised have been on my poorest and heaviest ground. On a plot of ground where the plow turned up the yellow clay at a depth of five or six inches, I have had the ground covered; covered so that you could hardly put your foot down anywhere in the patch without treading on a tomato, and not a cracked or rotten one among them. At another time I planted all the plants there were at that time of the now famous Turner Hybrid, in a patch of clay soil where young nursery trees had been grown for five years, and you can ask any nursery-man how much that leaves in the soil. Yet this patch produced tomatoes which astonished all beholders and led to its being placed at once upon the market; and right here I would say that the flavor and appearance of this variety have been so fine with me that I have obtained double price for my tomatoes since I have been growing it. In the last ten years I have had the handling of the first stock of three new tomatoes, each one of which has seemed near perfection when originated, yet each has been much superior to its predecessor. I mention this only to show how the craft of “assisting nature,” or gardening, is always progressing and gaining new interest in the mind of the gardener. There is a constant charm about it, that, once it takes possession of you, never lets go.

If the full-sized, green and partly ripe tomatoes are picked off when there is danger of frost, and placed under the sash of the cold frame, or on the floor of the cellar, they will ripen gradually, and though not of very fine quality, may be had fresh almost until Christmas; they must, of course, be entirely green when picked, to consume so much time in ripening.

If some plants of the golden or yellow varieties are planted, they will add greatly to the attractiveness of the dish when mingled with the red ones, served sliced in the ordinary manner. If you save your own seed, the earliest ripened specimens should be saved for that purpose, and should be of perfect shape and evenly ripened, with no core, crack or rot about them. The easiest way to clean this seed is, take a small box, knock the top and bottom off, and nail some wire fly screening over the bottom; take the fresh tomatoes, not rotten ones, as are frequently used, and squeeze the seeds into this sieve, throwing the pulp and flesh away; the seed can be washed free and clean by running clean water upon them, keep them constantly stirred and pick out the bits of pulp as they become free and float upon the top of the water, while the water and finer particles will pass off through the screening. When clean allow all the water to drain off and spread the seeds thinly on a smooth board or cloth in the sun; they should be stirred frequently, to prevent their adhering to each other when dry. If seeds are washed out in this manner and carefully dried, you can depend on every one growing, while from those saved in the ordinary manner, from tomatoes that have been allowed to heat and

rot, sometimes not one seed in a hundred will germinate.

VARIETIES OF TOMATOES.

EXTRA EARLY ADVANCE.--This variety is said to be the earliest in cultivation; at any rate, it is certainly a very early variety, and at the same time its fruits are of large size, of handsome, bright, red color and good quality; the solid flesh is free from the hard, green core present in the old varieties.

[Illustration: EXTRA EARLY ADVANCE.

EXTRA EARLY ADVANCE TOMATO.]

[Illustration: BURPEE'S CARDINAL TOMATO.]

BURPEE'S CARDINAL.--I had the pleasure of growing this variety before it was introduced, having been presented with a small packet of seed by the originator, who requested me to make a trial of its merits, and though it was an unfavorable season, and, as I wished to keep it separate, I could not plant it in my best tomato ground, its fine qualities exceeded all that he claimed for it. It is of beautiful appearance, every fruit being a brilliant cardinal red, uniform in shape, and without blemish or cracks. The flesh is of the same bright color, is firm and free from any rot or core, and is of superior flavor. The vine is very heavy bearing, and one of the best for all purposes that I know.

BURPEE'S CLIMAX.--This variety resembles somewhat the preceding kind, excepting that the fruits are a light crimson in color and do not average so large as does the Cardinal. The fruit matures early, ripens evenly, without core or cracks. The flesh is fine-flavored, solid, and produces but few seeds; it is a good kind for all purposes.

[Illustration: ESSEX EARLY HYBRID TOMATO.]

ESSEX EARLY HYBRID.--Very early, solid, rich flavored and handsome. It is of large size and grows perfectly smooth; the color is a bright pink, ripening evenly all over. It is very early, a great bearer, and, being solid, is a most excellent variety for shipping purposes.

GOLDEN QUEEN.--This is the best yellow tomato that I have ever grown. The fruit is of good size, handsome color, smooth, round shape, and superior quality. They should be in every garden, for the sake of the pleasing contrast they make when served with the red varieties.

[Illustration: GOLDEN QUEEN TOMATO.]

TURNER HYBRID.--This variety I consider _the_ tomato above all others, not only for its large size, handsome appearance and heavy cropping, but most of all for _its superior quality_, which far surpasses that of any other tomato that I have over eaten; and if there is one crop more than another that I pride myself upon, it is my tomatoes. Mr. Burpee, of W. Atlee Burpee & Co., gave me, in 1884, the small paper of seed sent them by a customer, and I planted it, as stated in the general chapter on tomatoes, and was so much pleased with it that since that time I have planted it altogether for my own use, with the single exception of a few plants of the Golden Queen. It is a rank, strong grower, with peculiar foliage, the vines strongly resembling potato tops. The fruit is very large and remarkably early for the size of the tomatoes; the average weight of the fruit is from twelve to eighteen ounces, so it will readily be seen that the size is very large, while, as above stated, I do not think it is possible to recommend the quality too highly.[15]

[Illustration: TURNER HYBRID TOMATO.]

TURNIPS.

With our hot, dry summers, turnips can only be raised satisfactorily as a fall crop. They can be grown as a second crop, after early sweet corn, potatoes or peas, and should be sown as soon as possible after the first of August. The ground should be plowed or run over two or three times with the cultivator, and then harrowed till it is as fine as it is possible to make it. If the seed is sown broadcast, some winter radish seed should be mixed and sown with it. The ground should be rolled after sowing, not only to compact the soil round the seeds, which is essential to good germination, but also to prevent washing by the September rains, if the ground is at all sloping. But where the finest turnips and a sure crop are desired, it is much better to sow our garden turnips in drills, one foot apart if you have a wheel hoe, or as narrow as you can cultivate, if you have not. This will tend to having the roots of even size, and the finest appearance, as they can be frequently worked. When about three inches high, or when beginning to form

bulbs, they should be thinned out to four or five inches apart in the rows, with the narrow hoe, leaving each bulb to stand by itself. It will be found that by this method, with careful culture, a larger as well as a much finer crop can be raised on the same ground than if they were sown broadcast, and that not half as much seed need be used, as it is carefully planted just where it is to grow.

[Illustration:

Illustration showing manner of storing turnips, beets, carrots, etc., in the garden for winter use. S, straw covering and ventilating chimney; D, covering of soil over the straw.]

About the third week in November, or before there is danger of the ground becoming hard, the turnips should be pulled and the tops cut off; take enough in the cellar for immediate use, and store the rest in heaps. Select a well-drained piece of ground, as directed for burying cabbages; it will be most convenient to have them near together; spread about two inches of straw on the ground, and heap the turnips upon it in the shape of a cone, not more than ten or fifteen bushels in a heap; cover this with straw, an inch or two thick, and bind it together at the top, and let it stick up a foot or so above the top of the cone; then cover the heap with four to six inches of soil, all but the straw top to the cone, which acts as a chimney or ventilator; the roots can thus be kept in good order throughout the winter. The surplus beets and carrots can be put in with the turnips, and the whole can be gotten at, any day when the temperature is above freezing, by making a hole in one side of the heap, taking out what you want, and carefully closing the opening again. The straw bottom and sides are not absolutely necessary, but are a great improvement and convenience, and will preserve the roots in a much cleaner and finer condition; the straw not only helping to keep out the frost, but at the same time providing ventilation for the heap.

VARIETIES OF TURNIPS.

EARLY RED, OR PURPLE TOP STRAP-LEAVED.--The best known and most generally planted variety. It is a quick grower, and the flesh is very fine grained and flavored. The red top of the bulb, which extends down to where it rests in the soil, adds very much to the appearance of this popular variety.

[Illustration: PURPLE TOP STRAP-LEAVED.]

[Illustration: EARLY WHITE FLAT DUTCH TURNIP.]

EARLY WHITE FLAT DUTCH.--This is a quick growing and very early variety. The skin and flesh are a clear white, and the flesh is solid; very sweet and juicy, and of mild flavor.

EXTRA EARLY PURPLE TOP MILAN.--This kind is said to be the earliest of all turnips, maturing two weeks earlier than the Early Red. The bulb is very flat, of medium size, quite smooth, with a bright purple top; leaves grow very short, making a small, neat top. The pure white flesh is solid, fine grained, and of superior quality, even in the largest specimens. It is an excellent keeper, retaining its good quality throughout the winter.

WHITE EGG.--As its name implies, this is a pure white turnip, of egg-shaped growth. It grows very quickly; has a thin white skin, and very solid, fine-grained white flesh. It is very sweet and juicy, of mild flavor and grows to a good size. It is a good variety for either early or late planting.

[Illustration: WHITE EGG TURNIP.]

WATERMELONS.

These are also supposed to require special location and soil, but can easily be raised in any garden where the climate is warm enough for cantaloupes, tomatoes, etc. What they most need is plenty of encouragement, in the shape of thorough cultivation and liberal feeding with well-rotted manure. The hills are prepared in the same manner as for cantaloupes, excepting that where the manure or compost can be obtained, a good-sized hole should be dug, and well-rotted manure or compost put in as liberally as the supply will admit of, even half a barrel to the hill. If this kind of hills can be made, you can plant with seed of some of the large growing varieties, and be sure of success, unless your season is very short. If the season is too short, or if you have not the manure for large hills, I would recommend some of the smaller fruiting varieties, as they are fully as fine in quality, ripen early, and set more melons than the larger kinds. From ten to a dozen seeds should be sown in each hill about the last of May, or when the temperature does not go below 60° at night. When they have got a good start, thin out to two or three plants in a hill.

[Illustration: HUNGARIAN HONEY MELON]

If your melons are of the tough-rind variety, as for instance the “Ironclad,” you can pick them off at the approach of frost, and by storing them in a cool, frost-proof cellar, have them in good condition till Christmas. Though my own opinion is that they lose their attractiveness when the hot weather is gone, still, it is always one of the main aims, in gardening, to have things out of season as well as at their regular period of ripening.

VARIETIES OF WATERMELONS.

HUNGARIAN HONEY.--This melon is one of the best for the small garden. Though not large, averaging eight to ten inches in diameter, it is perfectly round, so that there is a great deal of eating in one of them, while the quality is not equaled in any other variety. The melons ripen early, and the vines are vigorous in growth and very productive. As its name, “Honey Melon,” implies, it is sweet and luscious, and of a rich honey flavor, melting completely and leaving no stringy fibre in the mouth. The dark green skin, and intense brilliant red of the flesh, make a very striking appearance when cut.

BURPEE’S MAMMOTH IRONCLAD.--A large melon, of superior quality, and where there is room to grow them, will be found a profitable crop for market. Under ordinary culture, it frequently attains a weight of sixty to seventy pounds. They take their name of Ironclad from the exceeding toughness of the thin rind. Cutting into one is almost like cutting into sheet iron, though the flesh inside is fresh, crisp and melting. So strong is this rind, that I have stood on one of the smaller melons with a companion, our united weight of over 340 pounds not cracking the ripe flesh within in the slightest degree; and I have seen a wagon load of melons driven over one in the field without damaging it in the slightest. While it does not produce many melons to the vine, it more than makes up in size and weight what it lacks in quantity, being a heavy cropper when this is taken into account. The flesh is very beautiful, of a dainty red color and rich, sugary flavor. The flesh is never mealy, but always firm and solid. In shape this melon is oblong, its length often being two and a half times greater than its diameter.

[Illustration: BURPEE’S MAMMOTH IRON CLAD]

ICING, OR ICE RIND.--This is a dark, green-skinned melon, of nearly round shape. It is a favorite variety, on account of the solidity of its flesh, thin rind, and rich, luscious, sugary flavor.

CUBAN QUEEN.--The melons of this variety are very handsome and attractive in appearance; the skin being striped, dark, and light green, in a pleasing manner. The vines are strong and vigorous in growth, and bear enormous crops when well manured. The melons are large, very heavy, and of the finest quality. The rind is very thin, being scarcely more than half an inch in thickness on a large melon; the flesh is bright red, very solid, rich, and sugary. This is one of the very best varieties for general culture in all sections. The shape of this variety is oblong, being about twice its diameter in length.

[Illustration: BURPEE’S CUBAN QUEEN

111-lb CUBAN QUEEN WATERMELON.]

KOLB’S GEM.--The skin of this melon is striped, as in the Cuban Queen, but is not so handsome, as there is not the same amount of contrast between the two shades; the shape is much shorter, being nearly round. The flesh is bright red, and of good flavor; and owing to its tough rind is a very good shipping and keeping variety.[16]

RHUBARB, CURRANTS AND GOOSEBERRIES.

These three I would plant in the same row, in the small fruit plot or permanent part of the garden, mainly because a third of a row of each will afford an ample supply for a good-sized family, and all require nearly the same treatment. The plants of each are all set together, each in its own third of the row, not interspersed. The plants should be set as early in the spring as possible, or can be planted in the fall and well mulched with manure. The crowns of the rhubarb should be set an inch or two under the surface, and no stalks pulled until the second or third season; in the fall, when the ground is frozen hard, the old leaves should be pulled off and the row well mulched with long manure; in the spring this should be worked down to the roots, when the ground is fit to work, and the soil kept loose and free from weeds while the rhubarb is making its growth. The stalks can be pulled as soon as they are large enough for use, and can be pulled until they become so small as to be unfit for use; then dig in some fine manure or compost, and let it grow at will until fall, when the stalks will again be fit for use, though this second crop is generally allowed to go to waste, mainly, I think, through ignorance of the fact that it is just as palatable as in the spring, and that it can easily be canned for winter

use. Like asparagus, it must be liberally and continually fed, to have it in fine condition and of good size.

The currants and gooseberries are subject to the ravages of the currant worm, which cleans up every leaf and berry on the bushes just as they are about to ripen. To prevent this, the bushes should be dusted with white hellebore when the first worm makes his appearance; as this is a very strong poison many are afraid to use it; and, indeed, great care must be taken in using the fruit; still, the worms usually appear about the time the bushes are in bloom, and if promptly welcomed will have disappeared, and the poison be washed off the bushes before the fruit has formed. Any one who does not like to use the hellebore can dust the bushes with road dust or dry wood ashes every morning while the dew is still on the leaves; care should be taken that the _under_ side of the leaves should receive a good portion of whatever is used. There is still another way of getting rid of these pests, and that is by hand-picking them; but any one who has tried it will agree with me that it is a somewhat tedious process when done every morning for a couple of weeks.

When the fall comes these bushes should be well mulched, and in the spring, before the growth starts, the old wood should be cut out of them, care being taken not to trim them too severely; never take out more than a third of the wood, or you will trim away your crop of fruit for the season. When the spring opens, dig in the mulch and keep the ground well worked and free from weeds, as in the asparagus and rhubarb.

BLACKBERRIES, BLACK CAP RASPBERRIES AND RED RASPBERRIES.

The culture is the same for all these, and they should be planted in liberal quantities, so that there may be plenty to preserve, as well as a full supply for the table. In my own kitchen garden I have two rows of Wilson's Early Blackberry, one row Gregg Black Cap, and one row each of Philadelphia and Cuthbert Raspberries, and still the family cry for more, so I shall add about two rows of Wilson, Jr. Blackberries, and one of Lucretia Dewberry, in the spring. The dewberry will ripen before the blackberries, and thus prolong the season, as is already done with the two varieties of red raspberries.

The plants should be planted as early in the spring as the ground can be gotten into suitable condition, and if purchasing from a nursery, select those plants which are grown from root-cuttings, for they will not "sucker" so much, and where the garden is constantly well fed and cultivated this will save much in working, and the plants being carefully trimmed will last for years without replacing. The rows should be ten or twelve feet apart, so as to admit of free passage in cultivating and picking. As they do not grow so wildly until after the fruit has been picked, a couple of rows of peas or a row of early corn can be grown between each row. I have tried planting at closer distances, with the invariable result that by fall the berry patch was an impassable jungle. For manuring the berries coarse manure should be applied in the fall, or short, well-rotted manure in the spring; in either case plowing it under as applied; if plowed in the fall the furrows should all be thrown toward the rows, thus partly banking them over for the winter.

In the first warm days in the spring these bushes should have their trimming; all the old wood that has borne fruit will be dead and should be cut out at the ground. Three or four good healthy young shoots should be selected to each plant, cut off at three and a half or four feet in height, and the side shoots cut back to three or four inches; cut off all the rest of the suckers. This is important, for if too many are left there will be but a small crop of inferior fruit. When the whole patch has been trimmed and cleared up it should be staked; or each plant may be staked as trimmed, but the trimming will have to be left until a week or so later, as the stakes cannot be driven in the frozen ground. For this purpose I use old fence rails, sawing them in the middle and then splitting each piece into two or three stakes, or the large limbs, say one to two inches thick, left from trimming brush, can be used; the fence-rail stakes, however, last longer than the fresh cut poles, and are much more easily driven.

It will be a great help in picking-time if the row is gone over with a large pair of hedge shears, and the longest of the young shoots shortened in, so as to allow easy access to the row. Where it is more convenient, the bearing wood may be cut out as soon as the crop is gathered, thus throwing all the strength of the plant into the young shoots.

Where there is not plenty of manure, bone dust or phosphate can be sown on after the plowing in the spring and worked down with the harrow or cultivator. It, of course, takes a good deal of rope to tie all these and a good patch of grape vines up every spring, so I go to a printing office and buy the old Sisal rope which comes on the bundles of paper; this is strong, and can be bought very cheaply, as it is all in short lengths, in fact, most offices would be glad to oblige a good subscriber by giving it to him. The bushes should be planted eight feet apart in the row.

GRAPES.

I grow grapes between the rows of berry bushes, half way from each row, which are twelve feet apart. The vines are eight feet apart in the row; at every vine is planted an old fence rail, the ends squared off, and the bottom coated with coal tar before planting; these stand six feet above the surface, and from top to top runs a light pole or single strand of wire. The vines are tied up to the posts and out along the rail; this gives a clear space underneath for keeping the ground worked, and it bears the crop in the most convenient position for gathering. The vines should be trimmed early in February, that the wounds may contract and harden before the sap flows. The vines should be tied up with fresh rope; do not depend on any old ties, as, though they may look strong, the birds will pick them to pieces to make nests of. Trim the vines to long canes, two to four to each post, and divide them at the top, carrying half out the top pole or wire in each direction; cut the side shoots back to two eyes each, as these are the spurs that will furnish the fruit branches. If fruit is desired in finest condition a two-pound paper bag should be tied round the neck, to the stem of each bunch, placing the bunch inside, when the berries are about half grown; this preserves the grapes from mildew and, what is more destructive, the ravages of bees and birds.

STRAWBERRIES.

There should be one or two rows of strawberries across the garden; the rows four feet apart. It will be found a great deal easier to keep them free from weeds and to gather the fruit when grown in this way. The varieties, one early and one late, or both rows of a continuous bearing kind, should be of the perfect flowering character, as there are plenty of varieties of this character which are as good and prolific as any pistillate sort grown, and they are not so much trouble to grow, or as uncertain a crop. The plants should be set early in the spring, in well-manured ground, twelve inches apart in the row, and should be hoed and cultivated as frequently as possible. As the runners start lay them lengthways of the row and let them root in, keeping the soil loose and fine, so that they can easily take hold.

The blossoms should be kept picked off the season of planting, or they will take the strength of the young plant so that it will make but a feeble growth and no runners. In growing the plants in this way the runners should not be allowed to form a row more than one and a half feet wide, as this will be fully two feet in the second season, and as much as a picker can manage. The grass particularly should be kept out of the rows of young plants, or it will take a start in the spring and entirely crowd out the strawberries.

These rows should be set out every spring, taking the plants from the outside of the rows planted the preceding year, as it is almost impossible to keep them free from weeds after the first season, besides which they do not bear more than half so many, nor nearly such large berries, the second season. Unless the ground is very rich where the young plants are set, it is a good plan to sow a heavy coat of phosphate, bone, or, best of all, wood ashes, just before they are worked with the cultivator for the first time in the spring. The young plants should not be planted in land that has just been in sod, as it is full of white grubs, which will eat the plants off underground, and care should also be taken that the manure for the strawberry plot is not infested with them. These rows should be lightly covered with long manure, old hay or other litter, in the fall, after the ground has become frozen hard, so that they may be protected from rapid freezing and thawing; and if the covering is not too heavy, it can be left on in the spring and the plants will shoot up through it, leaving it as a mulch and serving to keep the berries clean, by saving them from contact with the ground, as does the straw mulching, from which the berry is generally supposed to take its name.

In selecting varieties choose those which are recommended as suitable for your soil, heavy or light, or such as have proved good in your immediate neighborhood, as some of the finest kinds are worthless in a different soil from that to which they are adapted. If especially fine, large berries are desired, the plants should be set in rows three feet apart, the plants twelve inches, as before, and all the runners kept cut off as fast as they appear. In this case heavy mulching is imperative, or the stools will be thrown out of the ground in the spring freezing and thawing. When the spring opens, the mulching should be cleared away from the crown of the plant, but should be allowed to remain on the ground surrounding the plant, as the weeds can easily be kept from such a patch, and fresh fertilizer applied. The patch may be continued in bearing for two or three seasons, but it will be found a great deal easier if a fresh patch is planted in new ground each year.

COMPOST.

This should be prepared in the early spring for use in the hills, and if it can be stacked in the fall and allowed to rot through the winter, it will be all the better. It can be composed of barnyard scrapings, well-rotted manure, chicken manure, night soil, or other strong fertilizer, mixed with at least an equal bulk of soil or ashes. This should be wet enough to rot thoroughly, but should not be allowed to lie exposed to the weather where its strength will leach away. When thoroughly mixed, I place it in old barrels under a shed and pour water on top of each barrel occasionally, to keep it rotting.

MANURE.

A good supply of manure should be either made or bought, as the garden should have a good dressing at least two years out of three; the third year I usually use a phosphate, but would use the manure if I could spare it, using also a good dressing of air-slaked lime every two or three years. The manner of applying the lime and phosphate is the same, but they must not be used the same season, as the lime will destroy the effect of the phosphate. They are sown on in the spring, after the ground has been plowed, and before harrowing, the harrow thoroughly mixing them with the soil. The supply of manure may be largely increased by pulling up the early peas, corn, cabbage stalks, etc., as fast as the crops are gathered, and adding them to the manure heap; this should be so located that all slops and waste from the house can be thrown upon it, so as to assist in keeping it constantly rotting; where corn stalks, tall weeds, etc., are put on the manure heap they should be cut into short lengths, with a corn cutter or other implement, to facilitate rotting and handling when the manure is drawn out.

SAVING SEEDS.

The gardener will consult his judgment and his pocketbook in buying seeds, as there are many varieties of which, if he has a good strain, he can save as good seed as he can buy; but the greatest care should be used in doing so, as the quality and quantity will both rapidly deteriorate if inferior specimens are selected from which to save seed. Thus it will not do to take off all the best ears of corn, or the tightest heads of lettuce, using the nubbins and runts for seed, or the next year the nubbins will predominate and the lettuce will go to seed without taking the trouble to form a head at all.

The best plan is to set apart a section of the row of each variety for seed, and not gather any for use from that part; here all the nubbins and inferior specimens could be pulled off, throwing the full strength of the plant into the finest fruits; and the same way with the vines; one or more hills, as desired, could be kept for the purpose of bearing seed only.

All seeds should be thoroughly cleaned and dried, and each package should be carefully marked with name and date before storing. The seed chest should be in some cool place where there is no danger of frost or very warm heat, and, most of all, no danger from dampness. It is important to have the date of saving the seed marked, so that when all is not used it may be kept, as frequently a crop fails from a bad season or other causes, and a new lot of equal merit cannot be obtained, the date serving to tell how good the seed is; seed of some vegetables retaining vitality for only two years, and others as long as ten years.

HOW AND WHAT TO GROW

IN A KITCHEN GARDEN

OF ONE ACRE.

THE SECOND PRIZE ESSAY.

BY MISS L. M. MOLL.

To insure success in horticulture, the first requisite is a deep, rich, well-drained soil. For a garden, nothing can be more important than good drainage. Soil properly drained is warmer, dries faster, and can be worked earlier in the spring; it is easier to work in a wet season, and more open and moist in a dry season. Taking for granted, then, that the ground has perfect drainage, it should be plowed deeply in the fall, so as to allow the frost to penetrate and sweeten the soil. In addition to this, the frost will be out sooner in the spring, and the superfluous moisture drained off more quickly, thus leaving the land in a workable condition at least a week earlier.[17]

Putting manure on the ground in the fall, or during winter, is a practice I would not recommend, because some of its most valuable portions are sure to be washed into the drains by the melting snow and spring rains, leaving the plants rather a meagre supply of nourishment to draw from when they come to need it most. The proper way to do is to give the ground a liberal spreading of thoroughly decomposed barnyard manure in spring, as soon as the land is in a workable condition.[18]

This should immediately be plowed in, and be followed with a sharp, weighted harrow, to thoroughly pulverize and mix the soil. This is important, as the surface of the soil is not so liable to harden or bake afterwards, if the ground is well worked in the spring. The soil is also permeated to a greater depth by the sun and air, causing healthier and quicker growth, consequently better and earlier vegetables. The form of our one-acre patch should, by all means, be a rectangle, made longer than wide, with the rows running

lengthwise, and all perfectly straight, and everything else so arranged that as much of the cultivation can be done by horse power as possible. But let me say right here, that no one should undertake the cultivation of a kitchen garden without being willing to do a reasonable portion of the work by hand. This part of the work can, however, be greatly lessened by using the various labor-saving garden implements, to be purchased at reasonable rates, of most seed firms.

If “variety is the spice of life,” it can certainly nowhere be more desirable than in the kitchen garden, which is to supply our table with its yearly demand for choice vegetables; I say _choice_, since every one having the care of a garden should strive to grow everything of the very best, and that, too, in great abundance and variety.

The most convenient mode of arranging the different kinds of vegetables is to; 1st, Place the perennial plants in one bed, running the entire length of the ground; 2d, Plant the vegetables side by side which are to remain out all winter, so as not to interfere with next spring’s plowing; 3d, Arrange side by side those varieties which require the whole season to mature; and, 4th, Put beside each other the quickly maturing kinds, which may be succeeded by other varieties, in order that the ground to be occupied by a second crop may be all in one piece.

The preliminaries being arranged, we are now ready to go into details, and to this end we shall first take under consideration the permanent bed, so called from the fact that it is to contain such perennials as asparagus, rhubarb, horse radish, artichoke, and chives; also parsley, and a collection of herbs, without which no garden is complete.

The herbs are placed here because they require a soil especially prepared for them, by the addition of either fine sand or sifted coal ashes, to make it mellow and dry.

[Illustration: DIAGRAM OF THE GARDEN.]

ASPARAGUS.

Asparagus, one of the best and earliest of spring vegetables, would be in universal use, but for the prevalent though erroneous idea that it is difficult to grow. Being a gross feeder, the soil can scarcely be too rich. Although the process of deep trenching is now being discarded, yet, to attain the best result it is necessary that a large quantity of rotted manure be worked into the bed, to a depth of at least 18 inches. Instead of losing two years’ time by raising plants from seed, send and get strong two-year old plants early in spring. Set these in the prepared bed, 18 inches apart each way, and about six inches deep. Give frequent and thorough cultivation, and as soon as the tops are ripe in fall, cut off and burn them, to prevent the nuisance of seedling asparagus about the garden. Next spring, and for at least fifteen years after, the bed should give a full crop, and should have a heavy dressing of manure put on each fall, which should be spaded in before the shoots appear in spring, together with a sprinkling of three pints of salt per square rod.

To facilitate gathering, make the bed of such a width as that the centre can be reached from both sides. Cut all shoots as soon as they appear, till the time for the final cutting, which will vary from the middle of May to the middle of June, according to latitude and your fondness for this most delicious plant.

RHUBARB.

Rhubarb, known familiarly as _Pie Plant_, succeeds best in deep, somewhat retentive soil. Coming, as it does, before berries or fruit, its acid leaf stalks form an admirable substitute. It may be raised from seed, but to get the quickest returns procure strong roots in spring, and plant them three feet apart each way, the ground having first been fertilized and dug to a considerable depth. Never permit a plant to exhaust itself by seed-bearing; stir the soil often, cover with coarse litter in fall, fork it over in the following spring, and you may rely upon a good supply of pie plant for many years to come.

HORSE RADISH.

The best is grown by planting 8-inch lengths of root grown the previous year. These young roots planted in spring, small end down, with the top two inches below the surface, in rich, well-cultivated soil, will form radish of large size and superior quality, in one season’s growth. After having several weeks’ growth rub off the young side roots from the newly-planted roots, to increase the size and insure a smooth, well-shaped root. See to it that no roots are scattered about the garden, as every piece of root, however small it may be, will, in a short time, become a strong plant, difficult to eradicate, and thus prove how annoying a good thing is in the wrong place.

GLOBE ARTICHOKE.

The Globe Artichoke is cultivated for its flower heads, which are cooked like asparagus, in an undeveloped state. On account of its hardiness, easy culture and perennial nature, this plant should be more generally grown. Plants raised from seed sown the previous year, set in any good garden soil two feet apart, with slight covering in winter, will remain in bearing a long time.

JERUSALEM ARTICHOKE.

The Jerusalem Artichoke needs only to be planted in order to thrive. Its _tubers_ can be made into quite palatable pickles, and I have seen instances where, in the absence of cucumber pickles, the artichoke tuber was prepared the same way and used as a substitute.

CHIVES.

Chives are perfectly hardy perennial little members of the onion tribe, and are grown exclusively for their tops, which are used wherever the flavor of onion is required. Planted in small clumps in any common garden soil, they will grow readily, and in time increase so as to render a division necessary. The tops appear very early in spring, and can be shorn throughout the season, hence this valuable little plant should have a place in every garden.

PARSLEY.

As parsley seed is so obstinate about germinating in spring, it does better if sown in autumn, as soon as ripe. Where that is not possible, the seed may be sown in spring, but “don’t look for the plants till you see them coming,” since parsley seed just comes up when it feels like coming up, and not before. The plants should be given a moist, rich soil and a partly-shaded situation. The curled sorts are ornamental, but the plain-leaved is best for general use in cookery. When once established, a supply can easily be kept up from self-sown seed.[19]

AROMATIC HERBS.

Aromatic or _Sweet Herbs_ are worthy of more attention than they generally receive. If cooks used them more freely, doctors would have less occasion for prescribing them. The soil of the herb bed should be mellow and warm, but not over-rich. Deep, fertile soil produces an increase in size and foliage at the expense of fragrance, strength and flavor. The seeds should be sown as early in spring as the ground can be prepared.

Sweet Basil, _Summer Savory_, _Sweet Marjoram_, _Sage_ and _Thyme_ are grown for their foliage, which is used for seasoning, while _Sweet Fennel_, _Dill_, _Coriander_, _Anise_ and _Caraway_ are chiefly prized on account of their aromatic seeds. Aside from being useful for culinary purposes, most of the above-named plants possess valuable properties.

This completes the permanent bed.

Before proceeding any further I wish to have it understood that hereafter, in the course of this paper, all seeds advised to be sown broadcast are to be sown in long, narrow beds, with narrow walks between the beds, for convenience in gathering the crop and to protect the plants from being trodden upon.

Where sowing in drills is advised, it is likewise to be understood that all drills are to be not less than eighteen inches apart, and the cultivation between them to be done with a hand cultivator or wheel hoe, followed by hand hoeing between the plants if necessary.

Where planting in rows is recommended, it is intended that all rows, unless otherwise mentioned, should be not less than two and a half feet apart, to admit of the cultivation with a one-horse plow or cultivator, followed also by hand hoeing around the plants or hills.

Concerning the distance plants should be apart in the rows or otherwise, it may be safely said that each plant should stand so that when fully matured its outside leaves will just touch those of its nearest neighbor. This rule does not apply to onions and root crops, which may stand closer.

Concerning the best varieties of the different kinds of vegetables the reader is referred to the catalogues of reliable seedsmen. I shall recommend such varieties as I know to be good from personal experience.

PARSNIPS AND SALSIFY.

Alongside of the permanent bed, plant parsnips and salsify. Parsnip seed germinates slowly and quickly deteriorates by age, therefore early sowing and seed of unquestionable freshness are of primary importance. The subsoil should by all means be thoroughly loosened by the subsoil plow, unless it is naturally of a loose, friable texture. When it is borne in mind that parsnip roots grow wholly under ground, and when well grown measure over eighteen inches in length, the necessity for this will be seen at once. Sow in drills and thin to five inches apart. Parsnips may safely be left in the ground all winter, as frost greatly improves them in saccharine quality.

Salsify or oyster plant, as the name implies, possesses the flavor of the oyster to a marked degree, and is highly esteemed by many on this account. It should have the same treatment in every respect as directed for the parsnip, and like it, too, is improved by frost. In the ground adjoining the parsnips and salsify, plant such vegetables as lettuce, spinach, radish, peas, bush beans, onions, kohl rabi, early cabbage, cauliflower, early potatoes and sweet corn. These mature nearly in the order named, and in time enough to be succeeded by other vegetables which will be mentioned hereafter.

LETTUCE, SPINACH AND RADISH.

Seed of lettuce, spinach and radish should be sown broadcast and as early as possible, with later sowings at intervals of about two weeks for a successive supply. Soil for lettuce and spinach should be of more than ordinary richness, and should contain sufficient moisture to insure rapid continuous growth. The best lettuce heads are raised by sowing seed in a hotbed and transplanting to the open ground when plants are two inches high. Cabbage varieties should be selected for this purpose. In this way I have grown heads of the _New York Lettuce_ to weigh two pounds each, under ordinary treatment. _Hanson_, _Burpee's Golden Heart_ and _Perpetual Lettuce_ are all good sorts. The _Cos varieties_ do best if tied up a few days before using, to blanch all the inner leaves.

The Radish will thrive in any good garden soil, but a light sandy loam is better than heavily manured ground. In order to be crisp and tender, the growth should be rapid and unchecked. I can recommend _French Breakfast_, _Golden Globe_, _White Stuttgart_ and _Chartiers_. The latter is of unusual merit.

PEAS.

As we all want green peas as early as possible, the seed should be planted early--the earlier the better. Peas will bear a great deal of cold without the slightest injury, either in the ground or after they are up. Sow in drills at the rate of one pint of seed to thirty-five feet of drill. To keep up a succession make a sowing of an early, medium, and a late variety at the same time. In about two weeks make another sowing as before. Soil for early varieties should be warm and very rich. Late varieties should be planted deeper than early sorts, but the soil should not be so rich, as late varieties are more productive on moist, cool ground, not over rich. _Philadelphia Extra Early_, _American Wonder_ and _Telephone_ can be relied upon. After trying various methods for training pea vines I am satisfied that brush is the most effective support. Place a few short twigs or sticks on each side of dwarf peas, to prevent them from leaning over and decaying on the ground, as is often the case in a wet season.

DWARF OR BUSH BEANS.

Dwarf or bush beans should not be planted before danger from frost is over. Being very tender, nothing is gained by planting earlier. They may be planted in hills one foot apart, with four plants to the hill, but the better way, I think, is to plant in drills, with plants three inches apart in the drill.

Seed should be covered lightly with mellow soil. Beans often fail to come up, from being covered too deeply, especially if there is much rain after planting. Two plantings of both early and late varieties, at intervals of two weeks, will give a supply until pole beans come in season. Beans should never be hoed while the foliage is wet, as that produces rust. _Black Wax_, _Early Valentine_ and _Golden Wax_ are standard sorts.

ONIONS.

Onions may be raised successfully either from seed or from sets. If to be grown from seed no time should be lost in getting it sown in the spring. Sow in drills and thin the plants when about the size of quills, disturbing the remaining plants as little as possible. For southern latitudes and for an early supply it is better to grow onions from sets planted three inches apart, in drills. Sets are small onions grown the previous year, from seed sown quite thickly. Sets may be planted very early, as they will not be injured even if the

ground should freeze after they are planted. _Wethersfield_ and _Danvers_ are good varieties. For extra large specimens, select _Italian varieties_.

KOHL RABI, EARLY CABBAGE AND CAULIFLOWER.

Seed of kohl rabi, early cabbage and cauliflower should be sown in a hotbed, and the plants transplanted to the open ground when four inches high.

Kohl rabi is grown for its turnip-shaped bulb, which is formed above ground, by the expansion of the stem. The bulb should be used while young and tender, as age detracts from its good quality. Set the plants eight inches apart in the row. For later use sow seed in drills and thin to the proper distance apart. When well grown and properly prepared for the table, the kohl rabi is one of the most desirable of vegetables, and should be in every garden. _Early White Vienna_ is the best variety.

Plant early cabbage in rows, with plants eighteen inches apart in the row. After trying several different sorts I have decided upon _Early Jersey Wakefield_, _Early Flat Dutch_, and _Fottler's Brunswick_, as the best varieties for this latitude, and, as the cabbage worm has made late cabbage an uncertain crop for several years past here, in southern Illinois, we have planted largely of the Early Flat Dutch cabbage and had it picked and put up before the cabbage worm made its appearance. This I know, from experience, to be better than the use of all the insect powders combined.[20]

To grow cauliflower to perfection, the ground needs extra heavy manuring, and the plants must be supplied with an abundance of water as soon as heads begin to form. Plants should stand the same distance apart as early cabbage. The outside leaves should be pinned together over the centre, to shield the head from the direct rays of the sun, which often cause it to turn green, thus rendering it inferior in quality or entirely unfit for use. _Early Snowball_ and _Erfurt_ are both good and reliable. Nowhere does success depend more on the quality of the seed than in the cauliflower.

SWEET CORN.

Sweet corn should be planted as soon as the ground is reasonably warm, in hills, three feet apart, three plants to a hill. The season for sweet corn can be greatly prolonged by planting early and late sorts, at intervals of a few weeks. There are many good early kinds, but I think the best late variety is _Stowell's Evergreen_, which produces ears of the largest size, that remain in a condition fit for the table longer than those of any other variety of sweet corn.

POTATOES.

If you wish to enjoy new potatoes early in the season, your seed potatoes must be planted as early in the spring as the ground can be prepared. Plant them one foot apart in the row and cover with the corn plow. I would advise the planting of medium-sized potatoes in preference to large ones cut to pieces. If large ones must be used cut them a few days beforehand, so that the newly cut surface may dry before planting, otherwise, there is danger of the pieces rotting in the ground, especially if there is much rain immediately after planting. The _Early Ohio_ gave us excellent returns for several years in succession.

* * * * *

We will next take under consideration that portion of the garden devoted to the vegetables requiring the greater part of the season to mature. The most important of these are:--

EGG PLANTS, TOMATOES, POLE BEANS, BEETS, CARROTS, LATE CABBAGE, CUCUMBERS, SQUASHES AND SWEET POTATOES.

Sow Egg Plant and Tomato seed in a hotbed and remove the young plants to a cold frame when three inches high, from whence do not remove them till the weather is settled and warm.

Egg Plant will repay the extra care it requires, and should be in every garden. Handle the plants very carefully in transplanting, and never remove them to the open ground before the nights are warm. At the North plants may be grown in flower pots plunged in a cold frame till the weather is sufficiently warm. Plants should stand 2½ feet apart in the row, and the soil should be very rich and warm. _New York Purple_ is the leading variety, but those who succeed with the _Black Pekin_ cannot fail to be pleased with its large, glossy fruits.

When all danger from frost is over, carefully transplant the Tomato plants from the cold frame to the open ground, to stand two feet apart in the row. As they grow tie them up on a trellis and remove all superfluous branches, so as to give the growing fruit the benefit of full sunshine, without which it will be of inferior quality and scarcely worth the having.[21] Nothing can be worse than allowing tomato plants to grow along the ground at will without any support. Better it would be not to grow any at all than to degrade them in that manner. Make a small trellis, four feet high, by nailing a few pieces of lath across small stakes driven into the ground. I regard _Livingston's Perfection_ as an excellent variety, and have grown extra large specimens of the _Mikado_, which, by the way, seems to have been cast in the same mold as the _Turner Hybrid_.[22] Be this as it may, I can heartily recommend either variety to all wishing to grow fine, solid, enormous-sized tomatoes.

POLE BEANS, as the name implies, require poles or some other support for the vines to twine upon. The poles must be set firmly, to prevent being blown over by the wind. Where poles are not procurable, the vines may be trained upon strings stretched up and down along two wires, which are stretched and firmly fastened to posts or stakes, one wire above and the other below. Pole Bean trellis, seven feet high, can be purchased, and will answer the purpose for which they are intended. The best pole bean of its kind is the _Large White Lima_. Being very tender, it should not be planted before the ground is warm. The beans will come up sooner if the eye in the seed is placed downward. The seed should be lightly covered with mellow soil, as this bean, considering its size, has less penetrating power in coming up than any other kind. In rainy seasons I have covered the seed with coffee grounds, which never became compact or hard from the beating rains, and nearly every bean came up nicely, while those covered with earth were almost a total failure.[23] The Large White Lima is generally considered difficult to grow, but I cannot say so, as I have grown it without much difficulty, and had beans to perfection by the pailful throughout the summer. Mine were planted in very rich soil and the rows were about four feet apart, three plants to a hill, and the hills two feet apart. If supported by a trellis, beans should be placed one foot apart in the row. The above applies to all pole beans, whether Limas or string beans. Of the latter class of beans I have found _White Creaseback_ a variety of great merit. _Southern Prolific_ and _Dutch Case Knife_ are also good. At the North, where the seasons are too short for the Large Lima, the _Small Lima_ or _Sieva_, as it is also called, should be planted.

Sow BEET and CARROT seed as early in spring as possible. Sow in drills and thin beets to five inches and carrots to three inches apart in the drill. To have Beets early we sometimes sow seed of an extra early variety in the hotbed and transplant to the garden when plants are a few inches high. The same may be done with early carrots. Sow _Early Scarlet Horn Carrot_ for early use and _Long Red Coreless_ for fall and winter. _Eclipse_ is one of the best early Beets and _Long Blood Red_ is the very best late variety.

Sow late CABBAGE seed in a seed bed, when danger from frost is over, and when plants are three inches high, plant them in rows three feet apart, with plants 2½ feet apart in the row. _Late Flat Dutch_, _Burpee's Surehead_ and _Large Late Drumhead_ are reliable sorts.

CUCUMBER and SQUASH seeds should under no consideration be planted before the weather is settled and warm, as the young plants are extremely tender and sensitive to cold. Cucumber hills should be four feet apart each way, and squash hills should be six feet apart. Scatter about a dozen seeds in a hill, and when the second pair of leaves have formed, remove all but three of the strongest plants. No fruit should be permitted to ripen on cucumber vines, as this greatly weakens the plant and prevents it from further setting fruit. Pinching off the tips of winter squash vines when they are about three feet long increases their productiveness. _Early Green Cluster_, _White Spine_, and _London Long Green_ are good varieties of cucumbers. The list of desirable squashes is long, but whoever grows the _Pineapple_ and the _Brazil Sugar Squash_ for early use, and the _Essex Hybrid_ and _Hubbard_ for winter use, will not be disappointed.

The term "hills," as used here and elsewhere in this paper, does not imply heaped-up soil, but simply means that several seeds are to be planted together in one place, on a level with the rest of the ground. This I have found to be better than heaping up the ground to form hills, which soon dry out and are difficult to water.[24]

The only plant requiring hills or ridges is the SWEET POTATO. Throw several furrows together with a plow and draw the soil up with a hoe, to form a tapering ridge; two feet high and three feet wide at the bottom. The plants, which are obtained by planting the tubers in a hotbed, are planted two feet apart on top of this ridge. Being of tropical origin, the sweet potato plants should never be planted till danger from frost is over. One hoeing is generally sufficient, as the vines soon cover the ridge, but these should not be allowed to take root, as that diminishes the productiveness of the plant. Late varieties are of better quality than the early ones.

PEPPERS, GUMBO AND LEEKS.

No garden is complete without at least a few plants of peppers, gumbo and leeks. To grow PEPPERS to perfection, the young plants should be grown in the hotbed and be transplanted to very rich soil, from twelve to eighteen inches apart, according to variety. When they commence blooming, a liberal quantity of hen manure should be strewn around each plant and be hoed in. This will increase the product wonderfully. _Burpee's Ruby King_ and _Golden Dawn_ are two superb new varieties.

GUMBO, or OKRA, is grown for its seed pods, which are used in soups and stews. Plant the seed eighteen inches apart, when the ground is warm, in spring, and use the pods while young and tender.

Sow LEEK seed very early, in a seed bed, in a sheltered place, if possible. When plants are about six inches long, transplant them to trenches six inches deep, with very rich soil at the bottom. Fill up the trenches as the plants grow, and later draw soil up to them. As a result, you will have fine, large leeks, blanched a foot long, which may be kept all winter if dug up with the roots on, and stored in moist sand in the cellar. Aside from being valuable for soups and salads, blanched leek makes an excellent dish when sliced and cooked like green peas. This fact does not seem to be generally known, as well-grown leek is so seldom seen in kitchen gardens.[25]

We will now go back again to the ground adjoining the parsnips and salsify. The early vegetables will mature and be harvested one after the other, so that there will be enough vacant ground in time for--

CELERY, ENDIVE, TURNIPS, WINTER RADISHES, KALE, CORN SALAD, WINTER LETTUCE AND WINTER SPINACH.

Sow CELERY seed in a hotbed or cold frame. When a few inches high, plant five inches apart, in a bed, in the open ground, which should be especially prepared for the purpose by extra heavy manuring. Let the plants remain in this bed, to grow strong and stocky. Never let the ground in this bed become dry; give thorough cultivation and cut off the tops of the plants once or twice, to make them grow stocky. When six or eight inches high, lift the plants carefully and set them six or eight inches apart, in trenches a foot wide and fourteen or more inches in depth. Several inches of rotted stable manure should be mixed with the soil at the bottom of the trench. When planting, firm the ground well around each plant. Supply enough water to keep the ground at the bottom of the trench very moist all the time. As the plants grow, press soil around the bottom of each plant and tie together at the top with string, to keep the stems straight and in an upright position. The blanching or earthing up is done by gradually filling up the trench with ground as the plants grow. Care should be taken not to get any ground into the hearts of the plants and never to earth up while they are wet. Sowing seed in the open ground and growing plants on the level surface may do for cool northern latitudes, but my experience is that it will not do here in southern Illinois. _Boston Market_ and _Crawford's Half Dwarf_ are as good as any of the taller varieties, and are more easily blanched.[26]

Seed of ENDIVE should not be sown early, as this plant is grown chiefly for late summer and autumn salad. In this latitude we sow at intervals from the middle of June to the 1st of August. Seed may be sown either broadcast or in drills, but the plants should be thinned so as to stand from six to nine inches apart. It may also be sown in a seed bed and be transplanted to the proper distance apart. When the plants are full grown, tie all the outside leaves together over the heart, to blanch the inner leaves, which will take about a week. To keep up a constant supply, some should be tied up every few days. Never tie up when the leaves are wet or they will soon decay. _Green Curled_ and _Batavian_ are both very good.[27]

TURNIP and winter RADISH seed may be sown from the latter part of July to the middle of August. If the ground is reasonably free from weed seeds it is advisable to sow broadcast, otherwise it is better to sow in drills. In either case, it is well to remember that the plants should be, like the first settlers, without a near neighbor. The size and quality of the turnips and radishes will depend, to a great extent, upon thin sowing of the seed, or, what is still better, a judicious thinning of the plants when young. The largest and sweetest turnips we have ever grown were of the _Purple Top Strap-leaved_ variety, and were grown as a second crop after onions. The seed was sown broadcast, and no further attention given the plants except thinning while young. In the same manner and on similar soil we raised _White_ and _Black Spanish_ winter radishes of excellent quality, that weighed from four to seven pounds each. The _Chinese Rose_, though not so large, is the handsomest and one of the best winter radishes grown. The _California Mammoth_ is a superb fall radish, but does not keep well in winter. The _White Stuttgart_ is regarded as a summer radish, but I have had it, grown as a winter radish, to keep firm and solid till April.

KALE, or BORECOLE, is a valuable plant for spring greens. The variety called _Dwarf German Greens_ is best for this purpose. Sow seed in drills about September 1st, and give thorough cultivation till the approach of cold weather. When winter sets in, give protection with a covering of straw or similar material, put on so as not to smother the plants. The most effective way of doing this is to place a layer of fine brush or cornstalks between the drills, to a height equal to or exceeding the height of the plants in the drills.

Then cover all with a layer of clean straw, six inches deep. The object of putting the brush between the drills is to provide an air cavity between the plants and the covering.[28]

CORN SALAD, or VETTICOST, is a valuable little plant which is used for salad, the same as lettuce. For spring use, sow the seed any time during the month of September, and at the approach of cold weather cover the bed with a few inches of straw or hay. It should be used very early in spring, as it soon runs to seed when warm weather sets in. Although this plant will bear neglect, it will also repay good treatment.

Seed of winter SPINACH and winter LETTUCE should also be sown during the month of September, and the plants should be protected with a covering of straw, or similar material, during winter. Put on part of the covering when the ground begins to freeze, and as the cold increases, add covering till it reaches a depth of four or five inches. In regions where heavy snowfalls can be depended upon, it may not be necessary to protect any of the above-named plants, but here and elsewhere, where winters are severe and the snowfall light, it is of the utmost importance to provide protection, or no success need be expected. _Hammersmith_ is the best winter lettuce, and _Round Leaf_ and _Prickly Winter_ are two good varieties of spinach for fall sowing.

The beds of kale, corn salad, winter lettuce and winter spinach should be arranged side by side, and alongside of the parsnips and salsify, so as not to interfere with the plowing of the ground in fall and in spring. As some of the parsnips and salsify will be left in the ground to be dug at leisure in spring, it is best to have all these vegetables side by side, so that when the parsnips and salsify[29] are dug, and the crop of kale, corn salad, etc., harvested, the whole ground can be plowed at once.

Before closing, a few words in regard to watering and transplanting may not prove amiss.

The best time for watering is in the evening. Though water may be given to the roots at any time, it should never be sprinkled on the foliage in the hot sun, as that causes brown spots or blisters where it comes in contact with the leaves. More injury than good results from beginning to water a plant, and then not keeping it up till the necessity ceases. As soon as the ground begins to get dry after watering, the soil should be stirred with the hoe. When you start to water a plant, do it thoroughly, so as to give the roots a soaking at every watering, or else do not water at all.

The main points to be regarded in transplanting, are handling the plant carefully, so as to injure the roots as little as possible, planting firmly and shading to prevent the sun from withering or scorching the leaves. It should be borne in mind, that it is not nature’s design that a plant should be transplanted, and we ought to show sympathy for a plant as well as for our fellow-creatures.

And now, having taken a walk with you through the kitchen garden, all I have further to say is, may you be favored with seasonable rain and sunshine, for, be it remembered, without the co-operation of the elements all our efforts are in vain.

Tools, 29. Cultivator, 31. Fire-fly hand plow, 33. Hand hoes, 35. Harrow, 30. Plow, 29. Roller, 31. Seed drill, 34. Shovels, 35. Spades, 35. Steel rakes, 35. Trowels, 35. Wheel hoe, 32.

Turnips, 151, 191. varieties of, 153. Early Red, or Purple Top Strap-leaved, 153, 192. Early White Flat Dutch, 153. Extra Early Purple Top Milan, 154. White Egg, 154.

Vetticost, 192.

Watermelons, 154. varieties of, 156. Burpee's Mammoth Ironclad, 156. Cuban Queen, 158. Hungarian Honey, 156. Ice Cream, 159. Icing, or Ice Rind, 157. Jordan's Gray Monarch, 159. Kolb's Gem, 158. Phinney's Early, 159.

Winter Cabbages, 55.

BURPEE'S

"HOW TO GROW"

* * * * *

PRIZE ESSAYS.

How to Grow Melons for Market.

Illustrated. Price 30 Cents, postpaid, by mail.

Our cash prizes for best essays on this subject were won by Mr. J. E. Rue, Jr., of Littleton, N. C.; Mr. J. T. Rosa, of Waverly Mills, S. C, and special prize for merit by Wm. Bailey, Esq., of Zanesville, Ohio. In order to present the subject to our readers in the most comprehensive and concise manner, we have compiled from these essays and our own experience a treatise that we think will be of value to every melon grower. It treats of both Musk Melons and Watermelons, with full information on the selection of soil, use and application of manures, selection of suitable and profitable varieties, planting the seed, destruction of insects, copious notes on cultivation of the crop, how to grow extra large melons, how and when to gather for market, and how to preserve for late use.

May be had of the Publishers of the Leading Agricultural Papers, or will be sent, postpaid by mail, upon receipt of price, by

W. ATLEE BURPEE & CO.,

Nos. 475 and 477 North Fifth Street, _Nos. 476 and 478 York Avenue_,

PHILADELPHIA, PA.

HOW TO GROW ONIONS,

WITH NOTES ON VARIETIES.

An exhaustive treatise, giving in full the prize essay, with the above title, by =Mr. T. Greiner=, of Monmouth County, N. J., also =Onion Growing by Irrigation=, by =Col. C. H. Arlie=, of Lake View, Oregon--carefully edited, with additional notes, including an article on the Growing of Sets, by W. ATLEE BURPEE. Besides other matter, it gives complete instructions on all the following subjects:--

Kinds of Soil--Preparation of the Soil--Manures: How, When and What Kinds to Apply--Seed--Sowing the Seed--Rolling--Cultivation--Hand Weeding--The Most Useful Implements--Thinning--Injurious Insects--Harvesting the Crop--How to Market--Storing for Winter--American Varieties of Onions--Italian Varieties--How to Grow, Handle and Store Onion Sets--Onion Growing by Irrigation--General Remarks.

Each subject connected with growing Onions is treated in a plain and practical manner, so that Farmers who have never before raised Onions for market can succeed, while even experienced growers may find facts of interest. ILLUSTRATED.

=PRICE, 30 CENTS.= Sent by mail, postpaid, to any address, upon receipt of price. Address

W. ATLEE BURPEE & CO., Seed Growers, PHILADELPHIA, PA.

HOW TO GROW

Cabbages and Cauliflowers

MOST PROFITABLY.

Illustrated. Price 30 cents, postpaid, by mail.

It is not too much to say that this book gives the most complete information on the successful growing of these important crops that has ever been published. The prize essays, carefully edited, are published in full, and are written by growers of long experience--Capt. G. H. HOWARD, of Suffolk County, L. I., well known as one of the most successful and largest growers of Cauliflower and Cabbage in America, and by Mr. J. PEDERSEN (BJERGAARD), of Denmark, a well-known writer and grower. To these is added an appendix that will interest our lady friends, giving, as it does, the recipes for cooking these vegetables, furnished for this book by Mr. S. J. SOYER, Chief Cook to His Majesty, the King of Denmark. The book treats fully on:--

How to succeed with CABBAGES--The Best Soils--The Cabbage a Greedy Feeder--Manures--Planting and Cultivation--Insects--Early Cabbages--Late Cabbages--Cutting and Marketing.

CAULIFLOWER--Selection of Land--Making Seed Bed and Sowing Seed--Cultivation--The Earliest Forcing of Cauliflowers--Cauliflowers in the Open Ground--For the Family Garden--Enemies of the Cauliflower--Varieties--Tying and Bleaching--Cutting--Trimming--Packing for Market--How to Keep for Winter Use--Numerous Recipes for Cooking Cabbage and Cauliflower.

Few, if any, crops that can be grown on the farm yield larger returns than Cabbage and Cauliflower, and with this “How to Grow” Treatise success is reasonably assured.

To be had of Houses handling Agricultural Books, or will be sent, postpaid, by mail, upon receipt of price by the Publishers,

W. ATLEE BURPEE & CO.,

PHILADELPHIA, PA., AND LONDON, ENGLAND.

ROOT CROPS

FOR

STOCK FEEDING,

AND HOW TO GROW THEM.

Illustrated. Price 30 Cents, by mail, postpaid.

This treatise has been carefully compiled from the prize essays, with copious additions from our own experience in growing these crops. It treats fully not only on HOW TO GROW, but also HOW TO STORE and HOW TO FEED, with notes on the relative value for stock feeding of the different varieties of Beets, Mangels, Carrots, Parsnips, Turnips and Ruta Bagas. In these days of low prices for cereals and high valuation of land, ROOT CROPS FOR STOCK FEEDING is a subject of the greatest importance to every progressive farmer desirous of making THE FARM PAY A PROFIT.

Sent by mail, postpaid, upon receipt of price.

BURPEE’S FARM ANNUAL.

A handsomely illustrated catalogue of the Best Garden, Farm and Flower SEEDS, Bulbs and Plants is published by January 1st of each year and mailed _gratis_ to all intending purchasers of seeds. Address

W. ATLEE BURPEE & CO., SEED GROWERS, PHILADELPHIA, PA.

FOOTNOTES:

[1] Miss Moll says that this rusting can be prevented by only hoeing the beans when the soil is dry. We would also particularly recommend _Burpee’s Perfection Wax_, a fine new variety, that has so far proved free from rust.--ED.

[2] See the method of covering the seed of Lima beans described by Miss L. M. Moll, and our note on the same.--ED.

[3] We would also particularly recommend _Burpee’s White Zulu_, a new variety of 1888. It is one of the earliest of pole beans, immensely productive, and the broad, handsome, white pods, eight to ten inches long, are of the choicest quality.--ED.

[4] The _Extra Early Express_, a new variety, just introduced from France, and seed of which we distributed for trial this year, has proved _eight to ten days earlier_ than the Etampes. The heads do not average quite as large as the Etampes, but are of equally as good quality and of the shape shown in the illustration on page 60.--ED.

[5] For years, Mr. Vandergaw, a large cabbage grower of Long Island, has had a _second-early_ cabbage fully as early as Early Summer and with much larger heads. This is known as _the Vandergaw Cabbage_, and is only now being generally introduced. The heads are very large and solid, of the shape shown in the illustration on page 64; it is a good keeper, and altogether a good variety, also, for winter use.--ED.

[6] Other distinct and good varieties of American onions are _Southport Yellow Globe_ and _Large Red Globe_, _Yellow Strasburg or Dutch_, and the _Extra Early Red_. For more complete information, invaluable to all who propose growing onions on a large scale for market, see the new book, “HOW TO GROW ONIONS, WITH NOTES ON VARIETIES,” an exhaustive treatise written by T. Greiner, of New Jersey, Col. A. H. Arlie, of Oregon, and W. Atlee Burpee.--ED.

[7] Equally as early is _Laxton’s Earliest of All_, which is a blue-seeded variety, of very fine quality and handsome appearance.--ED.

[8] The _Stratagem_ is also a remarkably fine pea, of the same type as _Pride of the Market_, except that the large, handsome peas are _wrinkled_.--ED.

[9] Mr. Darlington’s remarks on the varieties of peas would be incomplete without reference to two remarkable new peas, obtained by crosses made some years since, but only now (1888) being introduced. These peas have been called _Burpee’s Quantity_ (which is illustrated above), and _Burpee’s Quality_,--the former because it is the most productive of all, as many as ninety pods having been counted upon a single vine--the latter, because, while also very productive, it excels other varieties in its peculiarly rich, sugary flavor. Both varieties grow two and a half feet high, but will well repay brushing, and both are main-crop peas,--Burpee’s Quantity being ready for the table in about two months, and Burpee’s Quality in seven weeks from planting.

Probably no one in America is better posted as to the relative value in the garden of the different peas than MR. WILLIAM FALCONER, Glen Cove, N. Y., the well-known writer on garden topics. A few peas of Burpee’s Quantity (then known as No. 75) were sent to Mr. Falconer for trial. On Oct. 28th, 1887, he writes, “The pea, No. 75, I had from you this year has given me much satisfaction; indeed, so well pleased am I with it that I wish to grow it next year as a main crop. Season medium to late, grows two and a half feet, and in the way of Abundance; peas large, closely packed together in tight pods, and, when cooked, of capital quality. _Without any exception, the heaviest cropper among all my peas this year._”--ED.

[10] A very distinct and novel variety has just been introduced from China, under the name of _Celestial Pepper_. The small, nearly heart-shaped fruits are produced in great abundance, growing upright, and are of a beautiful creamy yellow color until fully ripe, when they turn coral red: the plant is handsome enough for the flower garden. Among the largest of the sweet, mild red peppers are _Spanish Monstrous_ and _Procopp’s Giant_, while among the hottest of all peppers is the _Long Narrow Cayenne_.--ED.

[11] While both of the varieties named are excellent for pumpkin pies, a new variety from Washington County, New York, is of superlatively fine quality. It is known as _The Quaker Pie Pumpkin_, as it had been kept for many years in a family of “Quakers,” or Friends, whose pumpkin pies became famous throughout the neighborhood.

The _Saint George_ or _Old Negro_ pumpkin of New England is also a great favorite, from the choice quality of its fine-grained flesh.--ED.

[12] We must differ with Mr. Darlington as to the usefulness of the winter radishes. Their fresh, pungent taste is very refreshing in winter, when there is such a scarcity of vegetables. The most popular varieties are the _California Mammoth White Winter_, _Chinese Rose Winter_ and the _Round Black Spanish Winter Radish_.--ED.

[13] For forcing, _Wood’s Early Frame_ is preferred to the Long Scarlet; it is of same shape, but not so long, and has less foliage. Other good early radishes besides those named are _Early Round Dark Red_, _Half Long Scarlet_, _Early Oval Dark Red_, _Early White Turnip_, _French Breakfast_ and the _White Tipped Turnip Radishes_. A variety of these handsome little radishes on the table is both attractive and appetizing.--ED.

[14] In addition to the varieties named, the _White Strasburg_, _Burpee’s Surprise_ and _Chartiers or Shepherd_ radishes are particularly valuable for summer use. The latter is very handsome, of large shape, clear rose color, shading off into pure white; it is also remarkable from the fact that it retains its fine quality, even when grown to an extraordinary size.--ED.

[15] Mr. Darlington has only named some of the best of the large varieties of tomatoes. The very small tomatoes, such as _Victoria_, _Red Cherry_, _Pear-shaped Yellow_ and _White Apple_, will be found useful and ornamental for preserving.--ED.

[16] In addition to the varieties named, we would recommend _Phinney’s Early_, as probably the best early melon of good size; also the _Ice Cream_ and _Jordan’s Gray Monarch_, as very choice melons of oblong shape.--ED.

[17] While, as stated, a well-drained soil is most desirable for the garden, and its value is not to be underrated, yet success in gardening can be had on almost any soil. The more unfavorable the circumstances, the greater credit is due the gardener, and many cannot afford expensive underdraining.--ED.

[18] The suggestion as to applying manure in the spring is good, as far as the well-drained land is concerned; where the land is not well-drained, however, more of the good properties of the manure are retained by applying the coarse manure in the fall, as it then fills the soil with decomposing vegetable matter.--ED.

[19] The parsley seed will germinate quickly if soaked in tepid water for twenty-four hours before planting. We must also take exception to the statement that the plain-leaved sorts are superior to the curled varieties for seasoning purposes.--ED.

[20] The reason here presented for not growing late cabbage, because the worms might damage some of them, is quite original, and about equal to not planting any potatoes, because the bugs might eat the tops. We can hardly conceive of a garden, however small, without late cabbage. For the prevention of the ravages of this pest we would suggest the use of alum water, as being sure, easily applied and entirely harmless to the user.--ED.

[21] It is the extreme richness of the soil, which is claimed by Miss Moll to be requisite to the growth of the Tomato, that, in her case, renders the use of the trellis and pruning necessary, as it induces too rank a growth of vine, covering the ground so that the sun and air cannot penetrate unless the vines are tied up. We can hardly see any _degradation_ in allowing the plant liberty to grow in the manner intended by nature. More than this, as seedsmen, we pride ourselves on the new and improved varieties of Tomatoes that we have introduced, and the finest we have ever grown--finest alike for size, color, quality and productiveness--have been grown on poor clay soil, that looked fairly yellow when at all dry, and we have never been able to equal them on either rich heavy loam, or on light soils. We would not undervalue the tying up of a few plants for early use, but claim that it is unnecessary for the general crop.--ED.

[22] As stated, these Tomatoes were undoubtedly originated from the same stock. We received the Turner Hybrid in the spring of 1884, a small packet of seed being sent us by one of our customers--Mr. J. W. Turner, of Iowa. This seed we had planted, and were surprised at the wonderful growth, size and quality of the variety, but unfortunately there were two distinct colors: some were a rich deep red and some a pale pink, of a not very attractive shade. So we grew it carefully for another season before sending out, that we might have them all of the best color. This, we believe, is not the case with the _Mikado_, as in our trial the two colors were present, although they both are evidently of the same origin.--ED.

[23] This idea of a mulch of light material to cover the freshly planted beans in a wet season is a very good one; but we would think that saving and applying _Coffee Grounds_ for a bean patch of the size it should be in a garden of one acre, would be a good deal like “emptying a hogshead of water with a teaspoon.” We would suggest the use of sand, sifted coal ashes, chaff or buckwheat hulls, as answering the purpose equally well, and as being much more readily obtained.--ED.

[24] We think that the melons, cucumbers, etc., get a better start (and we would include the pole beans) when the hill for seed is raised slightly above the surface, as it greatly lessens the danger of the young seedlings “damping off,” and instead of the watering, which is here claimed to be necessary, we would suggest a thorough loosening of the soil around the roots.--ED.

[25] Leek is both wholesome and palatable. We heartily endorse the words of recommendation, and trust that many readers will include it in their gardens. Kohl Rabi is another vegetable but little known in America, and which Miss Moll is also fully warranted in recommending.--ED.

[26] The plan here described involves much unnecessary labor. It takes considerable time to dig the trenches, and, unless the soil of the garden were unusually deep, this depth of trench, fourteen inches, would bring up and mix with the surface a great deal of very poor subsoil. As rich soil cannot be found at this depth, a liberal supply of manure must be put down, for the roots to feed upon, where it will not be available for any future crop, unless the trenches were located in exactly the same spot each year. The increase in the labor of digging for storage would be considerable over the plan of surface culture as recommended in Mr. Darlington’s treatise. Miss Moll gives as a reason the greater heat in her locality, to overcome which we would suggest planting between rows of tall-growing sweet corn, and also recommend the use of some of the self-blanching varieties of celery.--ED.

[27] Endive, commonly known in restaurants as _Chicorée_, is one of the most attractive and refreshing of salads. It is particularly appetizing when served mixed with lettuce, with plain French dressing.--ED.

[28] This is also sown at the same time as late cabbage, and grown in the same manner, being used as a fall and winter supply of greens, and we think is most palatable in this way.--ED.

[29] In this locality (Philadelphia), parsnips and salsify will start into growth, and become worthless for the table if left in the ground after it has become possible to work it in the spring. For a late supply, the roots should be dug and stored in a very cool cellar. This method does not interfere with the garden being all thoroughly plowed in the spring.--ED.

Transcriber's Notes:

1. Obvious printers', punctuation and spelling errors have been corrected silently.

2. Some hyphenated and non-hyphenated versions of the same words have been retained as in the original.

3. Superscripts are represented using the caret character, e.g. D^r. or X^{xx}.

4. Italics are shown as _xxx_.

5. Bold print is shown as =xxx=.

==========

The laws of contrast of colour

M. E. Chevreul

Project Gutenberg Release: September 27, 2025 · eBook #76939

Transcriber's Notes:

Underscores "_" before and after a word or phrase indicate _italics_ in the original text. Equal signs "=" before and after a word or phrase indicate =bold= in the original text. Small capitals have been converted to SOLID capitals. Illustrations have been moved so they do not break up paragraphs. Deprecated spellings have been preserved. Typographical and punctuation errors have been silently corrected. For the lines 788 to 888, the quote marks have been replaced with the actual text so that the lines can be broken up to fit within the 72 column width requirement.

[Illustration: PLATE IX.]

THE LAWS OF CONTRAST OF COLOUR:

AND THEIR APPLICATION TO THE ARTS OF PAINTING, DECORATION OF BUILDINGS, MOSAIC WORK, TAPESTRY AND CARPET WEAVING, CALICO-PRINTING, DRESS, PAPER-STAINING, PRINTING, MILITARY CLOTHING,

Illumination, Landscape, and Flower Gardening, &c.

BY M. E. CHEVREUL,

DIRECTOR OF THE DYE WORKS OF THE GOBELINS, ETC. ETC.

TRANSLATED FROM THE FRENCH BY JOHN SPANTON.

NEW EDITION,

With Illustrations printed in Colours.

LONDON: ROUTLEDGE, WARNE, AND ROUTLEDGE, FARRINGDON STREET. NEW YORK: 56, WALKER STREET.

1861.

PREFACE TO THE THIRD EDITION.

The present edition has been entirely revised; some obscurities cleared up, and a chapter on Military Clothing added. The application of Chevreul's reasoning will doubtless tend to a rational view of this much debated question. It affords much satisfaction to all concerned in the diffusion of the principles enunciated in this work, to observe that they are being generally applied in this country, thus realizing the hopes originally expressed by the translator.

TRANSLATOR'S PREFACE.

Colour, a universal source of enjoyment, so essential an element of decorative art, has not been hitherto the subject of such investigations as to place its powers, harmonies, and discordances among matters of scientific certainty. A few traditionary dogmas have been the only guide of ordinary workmen, while success in design, as well as in the higher regions of art, has been dependent upon that rare union of faculties vaguely denoted by the indefinite, unsatisfactory term, "taste."

The arrangement of colours in manufactures of English design—since the decline of mediæval art—has commonly been condemned as notoriously arbitrary, destitute of any reference to principle, and deficient in that satisfying richness and beauty which result from harmonious combinations. Although often overcharged with colour, and of costly elaboration, our manufactures have too often proved that the designer—in ignorance of a true, infallible standard—has mistaken gaudiness for splendour, and capricious strangeness for improvement; and, for want of a better claim to popular favour, has constantly sought it by "leaning on novelty, his fickle, frail support."

The established preference of French designs was shown, by the Great Exhibition of 1851, to be, in the main, well-founded; and one of the leading causes of the perfect success of some objects was found in the fact, that they had been designed and executed in accordance with a well-defined set of principles, extensively taught in France to designers, workmen, and others. These principles it is the purpose of this book to set forth, to illustrate, and to apply to every art of which the choice and arrangement of colours is an element.

The author, M. Chevreul, before the publication of this work, had gained high reputation by his researches in organic chemistry. In his “Considerations sur l’Analyse Organique,” he enunciated principles which, carried into practice in his “Recherches sur les Corps Gras d’origine animal,” opened the path which has been rendered illustrious by Liebig and others. But, being appointed Director of the Dye Works of the Gobelins, he was compelled to abandon these researches—the field in which, “having sown, he had, as it were, only to reap,”—that he might fully investigate the principles involved in the assortment of colours.

M. Chevreul’s earnest attention to this inquiry was continued during ten years, with ample opportunities for investigation. For twenty-five years he has been in the habit of lecturing to workmen, artists, &c. The undisputed superiority of those French manufactures in which these instructions have been fully carried out, has evinced his success and rewarded his exertions.

Aware of the important influence of such knowledge, the Chamber of Commerce of Lyons solicited and obtained from the French Government permission for M. Chevreul to lecture there to the artisans especially, to whom printed copies of the lectures were afterwards gratuitously distributed.

As the present Work contains the substance of these instructions, we may hope that our own industrious countrymen may not long be without a similar advantage.

The value of this book has been universally recognised, and it has already been translated into several languages, although but recently into our own. A recent critic has said, with equal truth and eloquence,—“Rarely has a subject of inquiry, so fraught with beautiful and ready applications, been presented to us. To be familiar with this book is to possess a new sense. Every object in art and nature speaks a new and exciting language. Colour becomes music to the eye. We become impatient of any violent infringement of the principles of harmony, and seek every opportunity of putting our newly-acquired knowledge into practice. The minuteness of investigation, and the copiousness of illustration which characterize this volume are truly remarkable; the most untutored mind cannot fail to understand it, if steady attention be given. As a preparation for a course of scientific study, it is invaluable, for it is an excellent example of the Baconian method of investigation.”

EXTRACTS FROM THE AUTHOR’S PREFACE.

In seeking to discover the causes of the complaint made of the quality of certain colours prepared in the dyeing laboratory of the Gobelins, I was at once convinced, that, although the complaints concerning the instability of the light blues, greys, and browns, might be well founded, there were others, especially those of a want of vigour in the blacks employed for the shadows of blue and violet draperies, which were not so; for, having procured black-dyed wools from the most celebrated dye works in France and other countries, and having found that they were not superior to those of the Gobelins, I saw that the want of vigour alleged against the blacks was owing to the colours contiguous to them, and that the matter was involved in the phenomena of _the contrast of colours_.

It was thus demonstrated to me that I had two absolutely distinct subjects to investigate, in order to fulfil my duties as Director of the Dye Works; the first being the contrast of colours, considered in the most general manner, both in relation to science and to its applications: the second—the chemistry of dyeing. These are the two centres around which have converged all my researches during the last ten years.

In fact, numerous observations made during several months, on the view of coloured objects, which were verified by my pupils and others, much accustomed in their profession to judge of colours and to appreciate the least differences between them, have been collected and described as well-known facts. Upon reflecting on the mutual relations of these facts, and in seeking the principle of which they were the results, I was led to the discovery of that which I have named the “Law of Simultaneous Contrast of Colours.” Thus this work is the fruit of the method _à posteriori_: facts are observed, defined, described, then generalized in a simple expression, which has all the characters of a law of nature. This law, once demonstrated, becomes a means, _à priori_, of assorting coloured objects so as to obtain their best possible effect, according to the taste of the person who arranges them; it becomes also a means of estimating whether the eyes are well organized for seeing and judging of colours; and whether painters have copied exactly the colours of known objects.

In reviewing the Law of Contrast with regard to its application, and in submitting to experiment all the laws which appear to me to result from it, I have been led to extend it to the arts of tapestry, to the various sorts of painting and printing, to illuminating, horticulture, &c. But, in order to anticipate the judgments of some readers, upon the value of the opinions I have advanced (2nd part, 2nd division) respecting the Gobelins and Beauvais tapestry and the Savonnerie carpets, I must state, that, being an entire

stranger to the inspection and direction of the works which are executed in the Royal manufactories, as well as to the choice of models, my views and opinions should be regarded only as those of an individual who has had frequent occasion to see and examine various artistic productions, on the preparation of which he could exercise no influence, the duties which attach me to the Gobelins being exclusively those of Director of its Dye Works.

THE LAWS OF

Harmony and Contrast of Colours.

INTRODUCTION.

1. A ray of solar light is composed of an indeterminate number of variously coloured rays, which are distributed into groups, termed _red rays, orange rays, yellow rays, green rays, blue rays, indigo rays, violet rays_.

2. But all the rays comprised in the same group, the red for example, are not identical in colour; on the contrary, they may be considered as differing more or less among themselves, although we recognise the impression they produce separately, as comprised in that which we ascribe to red light.

3. When light is reflected by an opaque white body, it is not modified in proportion to the variously coloured rays which constitute white light; but, 1. _If the body is not polished_, every point of its surface is to be considered as dispersing the white light which falls upon it, in all directions, into the surrounding space; so that the point becomes visible to an eye placed in the direction of one of its rays. We may easily conceive that the image of the body, in a given position, is composed of the sum of the physical points, which send to the eye so placed, a portion of the light which each point radiates. 2. _If the body is polished_, as, for example, the surface of a mirror, a portion of the light is irregularly reflected, as in the preceding case; while another portion is regularly reflected, giving to the mirror the property of presenting to an eye, suitably placed, the image of the body which sends its light to the reflector. One consequence of this distinction is, that if we regard two plane surfaces which reflect white light, and differ from each other only in polish, it will happen that where the unpolished surface is visible, all its parts will be equally, or almost equally, illuminated; while the eye, when in a position to receive only the light which it reflects irregularly, will receive very little light from the polished surface; but it will receive much more light when in a position to receive that which is regularly reflected.

4. If the light which falls on a body is completely absorbed by that body, so that it disappears from sight, as in falling into a perfectly dark cavity, then the body appears to us black; and it becomes visible only because it is contiguous to surfaces which reflect or transmit light. We know of no bodies which are perfectly black, and it is only because they reflect a little white light that we judge they have relief, like other material objects.

5. When light is reflected by an opaque coloured body, there is always a reflection of white light, and a reflection of coloured light; the latter is owing to the fact that the body absorbs or extinguishes within itself some of the coloured rays, and reflects the others. It is evident that the _absorbed_ coloured rays are of a different colour from the _reflected_ coloured rays; and farther, that if these be reunited with the former, white light will be reproduced. It is evident, also, that unpolished opaque bodies reflect irregularly white light, and the coloured light which makes them appear coloured; and that those which are polished reflect irregularly a portion only of these two lights, while they reflect regularly the other portion.

6. It thus appears, by what has been said concerning the physical composition of solar light, that if the whole of the coloured light which is absorbed by a coloured body were reunited with the whole of the light which it reflects, white light would result. Now, it is this property of two variously coloured lights, taken in a certain proportion, to reproduce white light, that we express by the words _coloured lights complementary to each other_, or _complementary colours_. It is in this sense that we say,

Red is complementary to Green, and _vice versâ_. Orange ” ” Blue, ” ” Greenish-Yellow ” Violet, ” ” Indigo ” ” Orange-Yellow, ”

7. It must not be supposed that a red body, a yellow body, &c. reflects, besides white light, only the red rays or yellow rays, &c., each of these bodies reflects also every sort of coloured rays; but, the rays which cause us to judge it to be red or yellow, &c., being more numerous than the others, produce more effect than they; yet, the latter have an undoubted influence in modifying the action of red and yellow rays upon the organ of sight. This explains the innumerable diversities of colour observable among various red bodies, various yellow bodies, &c. It is difficult not to admit that among these diversely coloured rays reflected by bodies, there are a certain number which, complementary to each other, must reproduce white light upon reaching the retina.

PART THE FIRST.

SECTION THE FIRST.

OF THE LAW OF SIMULTANEOUS CONTRAST OF COLOURS, AND OF ITS DEMONSTRATION BY MEANS OF EXPERIMENT.

CHAPTER I.

Manner of observing the Phenomena of the Simultaneous Contrast of Colours.—_Definition of Simultaneous Contrast._

8. If we look at the same time at two stripes of unequal tints of the same colour, or at two stripes of equal tints of different colours, in juxtaposition, that is to say, contiguous by one of their edges, the eye will perceive, if the stripes be not too wide, certain modifications; in the first case affecting the intensity of the two tints, in the second, the optical composition of the two colours so placed. Now as these modifications cause the colours to appear, when looked at together, more different than they really are, I have given to them the name of the _simultaneous contrast of colours_. The modification which affects the intensity of colour, I term _contrast of tone_; and the modification which affects the optical composition of the contiguous colours, I term _contrast of colour_.

The twofold phenomena of contrast of colour and contrast of tone may be readily shown by the following.

Experimental Demonstration of Contrast of Tone.

Plate A A■.

9. Let the two halves of a sheet of unglazed paper, about twenty inches square, be coloured clear grey, by a mixture of chalk and black; fix them, in any way, upon a piece of unbleached linen, placed across a window, at the distance of twelve inches asunder. Take two halves of another piece of similar paper B B■, but of a darker grey, and coloured with the same substances. Fix A next to B and place B■ twelve inches from B. (See Fig. 1.)

[Illustration: PLATE I.]

Upon looking at the four half-sheets for a few seconds, it will be seen that A contiguous to B will be lighter than A■, while B will seem darker than B■.

10. It is easy to demonstrate that the modification is not equally intense over the whole of the surfaces A A■ and B B■, but that it becomes gradually feebler from the line of contact. This may be proved by placing a card, so cut, that O and P may each present three grey stripes, as shown in Fig. 2, Plate 1. The stripes 1 1 are more modified than the stripes 2 2, and these are more so than the stripes 3 3. However, in order that this modification may be effected, it is not absolutely necessary that O and P should touch; for if the stripes 1 1 be covered, the stripes 2 2, 3 3 will be modified.

11. The following experiment, which is simply the result of the two preceding (9 and 10), is well suited to demonstrate the extent of contrast of tone. Upon a sheet of cardboard divided into ten stripes, each about a quarter of an inch broad, lay a uniform tint of Indian ink. As soon as it is dry, lay a second tint on all the stripes except the first. As soon as the second is dry, lay a third on all the stripes except the first and second, and so on of all the rest, so as to have ten flat tints, gradually increasing in depth from the first to the last. (See Fig. 3.) If ten strips of paper of the same grey, but each of a different tone, be laid upon a cardboard, in the preceding gradation, it will serve the same purpose.

Upon looking at the cardboard, it will be seen that the strips, instead of presenting flat tints, will each appear of a tone diminishing in intensity from the edge _a a_ to the edge _b b_. In the stripe 1, the contrast is produced simply by the contiguity of the edge _b b_ with the edge _a a_ of the stripe 2; in the stripe 10, it is simply by the contiguity of the edge _a a_ with the edge _b b_ of the stripe 9. But in each of the intermediate stripes 2, 3, 4, 5, 6, 7, 8, 9, the contrast is produced by a double cause; partly by the contiguity of the edge _a a_ with the edge _b b_ of the stripe which precedes it, partly by the contiguity of the edge _b b_ with the edge _a a_ of the darker tint which follows it. The first cause tends to raise the tone of the half of the intermediate stripe; while the second cause tends to lower the tone of the other half of the same stripe.

In consequence of this contrast, the stripes seen from a proper distance, resemble channels rather than flat surfaces. For, in the stripes 2 and 3 for instance, the grey is weakened from the edge _a a_ to the edge _b b_, presenting to the eye the same effect as if the light fell upon a channelled surface; there is however this difference, that in the real channelling the enlightened part would throw a reflection upon the dark portion.

12. Contrast of tone occurs with colours so called as well as with grey; thus to repeat the experiment (9), fig. 1, with the halves _o o_ of a sheet of paper of a light tint of a certain colour, and the two halves _p p_ of a sheet of paper of a darker tint of the same colour, it will be seen that _o_ contiguous to _p_ will be lighter than _o■_, and _p_ darker than _p■_. In short, it may be demonstrated as has been done (10) that the modification of colours in juxtaposition becomes weaker in proportion to their distance from the line of contact; and in order to observe this effect in bodies which are not contiguous, it is only necessary to experiment as described in (10).

[Illustration: PLATE II.]

The colours experimented upon must be as nearly as possible of equal intensity.

13. _Experimental Demonstration of Contrast of Colour._—If we arrange as before, the two halves of an unglazed coloured sheet of paper, and two halves of another sheet of a different colour, but as nearly as possible of equal intensity, or rather of _tone_ (8), upon looking at the four half-sheets _o o■, p p■_ for a few seconds, we shall see that _o_ differs from _o■_ and _p_ from _p■_; consequently the two half-sheets, _o p_, seem to undergo a reciprocal modification of tint, which is rendered apparent by comparing their colours with those of _o■_ and _p■_.

14. No 1. { Red inclines to Violet. { Orange ” Yellow. 2. { Red ” Violet. { Yellow ” Green. 3. { Red ” Yellow. { Blue ” Green. 4. { Red ” Yellow. { Indigo ” Blue. 5. { Red ” Yellow. { Violet ” Indigo. 6. { Orange ” Red. { Yellow ” Bright Green. 7. { Orange ” Bright Red. { Green ” Blue. 8. { Orange ” Yellow. { Indigo ” Blue. 9. { Orange ” Yellow. { Violet ” Indigo. 10. {Yellow ” Bright Orange. { Green ” Blue. 11. { Yellow ” Orange. { Blue ” Indigo. 12. { Green ” Yellow. { Blue ” Indigo. 13. { Green ” Yellow. { Indigo ” Violet. 14. { Green ” Yellow. { Violet ” Red. 15. { Blue ” Green. { Indigo ” Deep Violet. 16. { Blue ” Green. { Violet ” Red. 17. { Indigo ” Blue. { Violet ” Red.

15. It thus appears from the experiments described in this chapter that two coloured surfaces in juxtaposition, viewed simultaneously, present to the eye two modifications—one relative to the depth of tone of their respective colours, and the other relative to the physical composition of those colours.

CHAPTER II.

The Law of the Simultaneous Contrast of Colours, and the Formula which represents it.

16. After I had assured myself that the preceding phenomena were constant for my sight when it was not fatigued, and that many persons, accustomed to judge of colours, saw them as I did, I sought to reduce them to an expression sufficiently general to render it possible to predicate the effect which would be produced upon the organ of vision by the juxtaposition of two given colours. All the phenomena that I have observed seem to depend upon a very simple law, which in its most general sense may be enunciated in these terms: When two contiguous colours are seen at the same time, they appear as dissimilar as possible, both with regard to their optical composition and their depth of tone. Therefore there may be at once simultaneous contrast of colour, properly so called, and simultaneous contrast of tone.

17. Now two colours in juxtaposition, _o_ and _p_, will differ from each other in the greatest possible degree when the complementary of _o_ is added to _p_, and the complementary of _p_ is added to _o_; indeed by the juxtaposition of _o_ and _p_, the rays of the colour _p_, which _o_ reflects when it is seen alone, and which are active in that case, cease to be so when _o_ and _p_ are in juxtaposition. Now under these circumstances, each of the two colours, losing what it has analogous to the other, must be so much more different from it.

18. The following formulæ will illustrate this:—

Let us represent—

The colour of the stripe O by the colour _a plus_ white B, ” ” P ” _a■ plus_ white B■, the complementary colour of _a_ by C, ” ” _a■_” _c■_, the colours of the two stripes seen separately are— Colour of O = _a_ + B; colour of P = _a■_ + B■; by juxtaposition they become—

Colour of O = _a_ + B + _c■_, P = _a■_ + B■ + _c_.

We will now show that this expression amounts to taking away the rays of _a■_ from the colour _a_ of O (15), and to taking away the rays of the colour _a_ from _a■_ of P.

For let us suppose—

B reduced into two portions, white = _b_ + white = (_a_■ + _c_■),

B■ reduced into two portions, white = _b_■ + white = (_a_ + _c_).

The colours of the two stripes seen separately are—

The colour of O = _a_ + _b_ + _a_■ + _c_■, and the colour of P = _a_■ + _b_■ + _a_ + _c_.

By juxtaposition they become—

The colour of O = _a_ + _b_ + _c_■, and the colour of P = _a_■ + _b_■ + _c_.

An expression which is evidently the same as the former, except for the values of B and B■.

19. I have said that simultaneous contrast may at the same time affect the optical composition of colours, and the depth of their tone; consequently, when colours are not of the same depth, that which is deep appears deeper, and that which is light appears lighter; that is to say, the former appears to lose white light, while the latter seems to reflect more of it. Thus _there may be, in looking at two contiguous colours, simultaneous contrast of colours and simultaneous contrast of tone_.

CHAPTER III.

The Law of Simultaneous Contrast of Colours demonstrated by the Juxtaposition of a certain Number of Coloured Bodies.

20. Let us now apply the above formula to the seventeen observations of Chapter I., and we shall see that the modifications of contiguous colours are precisely those which would result from the addition to each of them of the complementary of the contiguous colour (18). The rank these colours occupy in Chapter I. may be readily noted, as I have attached to each the number applied to it in that chapter. And for the complementary of each colour see (6). (See Plate II.)

Orange and Green, 7. 21. Orange, the complementary of Blue, being added to Green, makes it Bluer or less Yellow. Green the complementary of Red being added to Orange makes it Redder less Yellow.

Orange and Indigo, 8. 22. Orange, the complementary of Blue, being added to Indigo, makes it Bluer or less Red. Green the complementary of Red being added to Orange makes it Redder less Yellow.

Orange and Violet, 9. 23. Orange, the complementary of Blue, being added to Violet, makes it Blue or less Red. Violet the complementary of Orange-yellow being added to Orange makes it Yellower less Red.

Green and Indigo, 13. 24. Green, the complementary of Red, being added to Indigo, makes it Redder or more Violet. Indigo the complementary of Orange-yellow being added to Green makes it Yellow.

Green and Violet, 14. 25. Green, the complementary of Red, being added to Violet, makes it Redder. Violet the complementary of Green-yellow being added to Green makes it Yellower.

Orange and Red, 1. 26. Orange, the complementary of Blue, being added to Red, makes it Violet or Crimson. Red the complementary of Green being added to Orange makes it Yellower.

Violet and Red, 5. 27. Violet, the complementary of Green-yellow, being added to Red, makes it Orange-yellow. Red the complementary of Green being added to Violet makes it Indigo.

Indigo and Red, 4. 28. Indigo, the complementary of Orange-yellow, being added to Red, makes it Orange. Red the complementary of Green being added to Indigo makes it Blue.

Orange and Yellow, 6. 29. Orange, the complementary of Blue, being added to Yellow, makes it Greener. Yellow the complementary of Indigo being added to Orange makes it Redder.

Green and Yellow, 10. 30. Green, the complementary of Red, being added to Yellow, makes it Orange. Yellow the complementary of Indigo-violet being added to Green makes it Blue.

Green and Blue, 12. 31. Green, the complementary of Red, being added to Blue, makes it Indigo. Blue the complementary of Orange being added to Green makes it Yellower.

Violet and Blue, 16. 32. Violet, the complementary of Greenish-yellow, being added to Blue, makes it Greenish. Blue the complementary of Orange being added to Violet makes it Redder.

Indigo and Blue, 15. 33. Indigo, the complementary of Orange-yellow, being added to Blue, makes it Green. Blue the complementary of Orange being added to Indigo makes it Violet.

Red and Yellow, 2. 34. Red, the complementary of Green, being added to Yellow, makes it Green. Yellow the complementary of Indigo-violet being added to Red makes it Violet.

Red and Blue, 3. 35. Red, the complementary of Green, being added to Blue, makes it Green. Blue the complementary of Orange being added to Red makes it Orange.

Yellow and Blue, 11. 36. Orange-yellow, the complementary of Indigo-violet, being added to Blue, makes it Indigo. Blue the complementary of Orange being added to Yellow makes it Orange.

Indigo and Violet, 17. 37. Indigo, the complementary of Orange-yellow, being added to Violet, makes it Red. Violet the complementary of Greenish-yellow being added to Indigo makes it Bluer.

38. It is evident that, all other things being equal, the modifications of contiguous colours will be so much the more marked, as the complementary colour C or C■, which is added to each of them, differs more from them; for the complementary C■ which is added to the colour O, is identical with it, as the complementary C is identical with the colour P to which it is added; and the modifications of O and P will simply augment the intensity of their colours. But are there yet any two bodies known which present to the observer two pure colours perfectly complementary to each other? Certainly not; all those which are coloured by reflection reflect (7), besides white light, a great number of rays of various colours. We cannot instance a _red_ body and a _green_ body, or an _orange_ and a _blue_, or an _orange-yellow_ and an _indigo_, or a greenish-yellow and a _violet_, which reflect pure or mixed colours, absolutely complementary to each other. So that the juxtaposition of these colours produces only a simple _augmentation of their intensity_. Hence, although it is less easy to verify the law of contrast with respect to red and green, or orange and blue, &c., than with respect to those which are the object of the seventeen experiments just described (15), yet, upon applying it to the former, it will be seen that their colours acquire a most remarkable brilliancy, strength, and purity. This result, perfectly conformable to the law, may be easily understood: for example, an orange-coloured object reflects blue rays, as a blue object reflects orange rays (7). Hence, when a blue stripe is put in contact with an orange stripe, although it is admitted that the first appears to the eye to receive blue from the orange of the second, as this appears to receive orange from the blue of the blue stripe; or what is the same thing, that the blue stripe appears to destroy the effect of the blue rays of the second stripe, as these appear to destroy the effect of the orange rays of the blue stripe—it is evident that the two colours so contrasted must purify each other, and become more intense. But the blue may incline to green or violet, and the orange to yellow or red; that is to say, the modification may not only affect the intensity of the colour, but also its physical composition. However, if this latter effect take place, it is always much more feeble than the first. Besides, if you look several times at the same coloured stripes, you will see that the blue which at first had appeared to you greenish will afterwards appear inclining to violet; and that the orange, which had appeared at first yellowish, will incline to red; so that the phenomena of modification, as it affects the physical composition of colour, will not have the constancy of those which are the subject of the preceding seventeen observations (15). I now proceed to state the observations I have made on colours which are most nearly complementary to each other.

Red and Green.

39. _Red,[1] the complementary of Green, placed by the side of Green, increases its intensity._

Green, the complementary of Red, placed by the side of Red, increases its intensity.

[1] In the original French Edition there is evidently a confusion of terms in this and the two following articles (39, 40, 41, 42). The Red is there represented as placed in juxtaposition with _red_, and green with _green_, and so on with the other instances; orange and blue; orange-yellow and indigo; greenish-yellow and violet; instead of being made by contrast with their respective complementaries to intensify each other.

Such is the theoretical result, the experimental result entirely agrees with it. When we place a green, inclining more to yellow than to blue, side by side with, 1st, a slightly orange-red, 2nd, a slightly crimson-red, and 3rd, an intermediate red, and repeat our observations several times on each of these assemblages of colour, we shall observe different results; that is to say, in one case the red will appear more orange and the green yellower, and in another the red will appear more violet and the green bluer. We shall find also that the change may be attributed as much to a difference in the intensity of the light upon the colours as to fatigue of the eye.

When we place a green, inclining rather to blue than to yellow, side by side with, 1st, a slightly orange-red, 2nd, a slightly crimson-red, and 3rd, an intermediate red, the results are the same as with the first green, but with this difference,—that in the assemblage of bluish-green and of slightly crimson-red, observed several times, the green and the red appear almost constantly yellower than they are separately. A result very easily understood.

Orange and Blue.

40. _Blue, the complementary of Orange, placed by the side of Orange, increases its intensity._

Orange, the complementary of Blue, placed by the side of Blue, increases its intensity.

Upon repeating these observations with a deep blue and an orange which is not too red, the two colours appear commonly to become redder.

Orange-Yellow and Indigo.

41. _Orange-yellow, the complementary of Indigo, placed by the side of Indigo, increases its intensity._

Indigo, the complementary of Orange-yellow, placed by the side of Orange-yellow, increases its intensity.

[Illustration: PLATE III.]

Greenish-Yellow and Violet.

42. _Greenish-yellow, the complementary of Violet, placed by the side of Violet, increases its intensity._

Violet, the complementary of Greenish-yellow, placed by the side of Greenish-yellow, increases its intensity.

The result of observation is almost always in conformity with this law.

43. According to the law of the simultaneous contrast of colours, and the insensible gradation of modification, beginning at the contiguous edges of the colours in juxtaposition (11), we may show, by means of coloured circular spaces, the modifications which the principal colours induce in those which are contiguous to them.

Place wafers, circular pieces of paper, or any other convenient material about an inch and a half in diameter, coloured red, green, orange, blue, greenish-yellow, violet, indigo, and orange-yellow, each separately upon a sheet of white paper; then tint the white paper around the circle with its complementary colour, gradually softening it off from the coloured circle, when it will be found that

The Red circle tends to colour the surrounding space with its complementary Green. Green ” ” Red. Orange ” ” Blue. Blue ” ” Orange. Greenish-yellow ” Violet. Violet ” ” Greenish-yellow. Indigo ” ” Orange-yellow. Orange-yellow ” Indigo.

These figures are designed to exhibit the effects of contrast to those persons who, not having studied physical laws, are, notwithstanding, desirous of understanding these effects.

CHAPTER IV.

On the Juxtaposition of Coloured Surfaces with White.

44. When white bodies are viewed simultaneously with coloured bodies contiguous to them, they are sensibly modified. I confess that the modification is too feeble to be determined with absolute certainty while we are ignorant of the law of contrast; but, understanding that, and knowing the modifications that white undergoes in connexion with certain colours, we shall not fail to recognise this modification in special cases, provided the colours opposed to the white be not too deep.

Red and White.

45. Green, complementary to Red, being added to White, the Red appears more brilliant and deeper.

Orange and White.

46. Blue, complementary to Orange, being added to White, the Orange appears more brilliant and deeper.

Greenish-Yellow and White.

47. Violet, complementary to Greenish-yellow, being added to White, the Yellow appears more brilliant and deeper.

Green and White.

48. Red, complementary to Green, being added to White, the Green appears more brilliant and deeper.

Blue and White.

49. Orange, complementary to Blue, being added to White, the Blue appears more brilliant and deeper.

[Illustration: PLATE IV.]

Indigo and White.

50. Yellowish-orange, complementary to Indigo, being added to White, the Indigo appears more brilliant and deeper.

Violet and White.

51. Yellowish-green, complementary to Violet, being added to White, the Violet appears more brilliant and deeper.

Black and White.

52. Black and white, which may be considered in some respects complementary to each other, become, conformably to the law of contrast of tone, more different than when seen separately. This results from the effect of the white light, which is reflected by the black (4), being more or less destroyed by the light of the white stripe. By an analogous action, the white heightens the tone of the colours to which it is contiguous.

CHAPTER V.

On the Juxtaposition of Coloured Bodies with Black.

(See Plate 9, Page 54.)

53. A black surface being deeper than that which is contiguous to it, the contrast of tone tends to deepen it still more, while it tends to lower the tone of the contiguous colour; as on the other hand white, placed in juxtaposition with it, would heighten it. So much for contrast of tone.

54. Black surfaces reflect a small quantity of white light (4), and this falling upon the retina simultaneously with the coloured light of a contiguous body, it is evident that the black surface must appear tinted with the complementary of the coloured light; but it will be a weak tint, since it is displayed upon a ground which has but a feeble power of reflecting light. So much for the contrast of colour.

55. The lowering of the tone of the colour contiguous to the black is constantly observed; but a very remarkable fact is the weakening of the black itself, when the contiguous colour is deep, and of a nature to give a luminous complementary, as orange, orange-yellow, greenish-yellow, &c.

Red and Black.

56. Green (the complementary of Red), when placed by the side of Black, makes it appear Reddish. The Red looks clearer, partaking less of Orange.

Orange and Black.

57. A Blue (the complementary of Orange), when placed by the side of Black, causes it to appear less brilliant, or somewhat rusty, while Orange by the side of Black appears more brilliant in colour.

Greenish-Yellow and Black.

58. Greenish-yellow (the complementary of Violet), when placed by the side of Black, gives it a Violet tint, whilst the Greenish-yellow becomes clearer and more Green; but there are some kinds of Yellow which are weakened by the side of Black.

Green and Black.

59. Red (the complementary of Green), when placed by the side of Black, causes the Black to appear more Violet or Reddish; whilst Green by the side of Black becomes slightly Yellower.

[Illustration: PLATE V.]

Blue and Black.

60. Orange (the complementary of Blue), when placed by the side of Black, causes it to appear brighter, while the Blue becomes clearer and somewhat Greener.

Indigo and Black.

61. Orange-yellow (the complementary of Indigo), placed by the side of Black, causes it to look much brighter. The Indigo also appears brighter.

Violet and Black.

62. Violet (the complementary of Greenish-yellow), when placed by the side of Black, lightens it up; whilst the Violet becomes more brilliant and clear, and somewhat Reddish.

CHAPTER VI.

On the Juxtaposition of Coloured Bodies with Grey.

(See Plate 10, Page 58.)

63. As the brilliancy of the light reflected by white bodies is one of the principal causes which render the sight insensible to the modifications produced in white by the juxtaposition of coloured bodies; and, on the other hand, as the feeble light reflected from black bodies is unfavourable to our perception of the modifications which they sustain from the proximity of coloured bodies, especially when the complementary of the colour of these bodies is but slightly luminous, it may be conceived that grey bodies, judiciously selected with regard to their depth of tone, would, by contiguity to coloured bodies, exhibit the phenomena of contrast of colour in a more striking manner than either black or white bodies would.

Red and Grey.

64. Grey appears Greenish by receiving the influence of its complementary Red.

The Red appears purer, less Orange perhaps.

Orange and Grey.

65. Grey appears Bluer by receiving the influence of its complementary Orange.

The Orange appears purer, more brilliant, Yellower perhaps.

Yellow and Grey.

66. Grey appears to incline to Violet by receiving the influence of its complementary Yellow.

The Yellow appears more brilliant, and yet less Green.

Green and Grey.

67. Grey appears to incline to Red by receiving the influence of its complementary Green.

The Green appears more brilliant, Yellower perhaps.

Blue and Grey.

68. Grey appears to incline to Orange by receiving the influence of its complementary Blue.

The Blue appears more brilliant, Greener perhaps.

Indigo and Grey.

69. Grey appears to incline to Orange by receiving the influence of its complementary Blue.

The Blue appears more brilliant, Greener perhaps.

Violet and Grey.

70. Grey appears Yellowish by receiving the influence of its complementary Violet.

Violet appears fresher, less dull.

70_a_. The grey, which was the subject of the above experiments, was as free as possible from every colouring matter foreign to black; it belonged to the scale of normal black (see Part II., 164)—that is to say, it resulted from a mixture of the purest possible black and white materials. By juxtaposition with white, it appeared deeper, and the white appeared more pure; while by juxtaposition with black, it appeared lighter and more rusty, and the black appeared deeper.

70_b_. One result of the complementaries of colours in juxtaposition with grey being more perceptible than when these colours are juxtaposed with white or black, is, that if instead of a _normal grey_, we juxtapose a _grey, tinted_ either with _red, orange, yellow_, &c., these tints will be greatly heightened by the complementaries added to them. For example, a bluish grey will receive a very perceptible increase of blue from its proximity to orange, and a yellowish-grey will take a perceptible green tint from the same proximity.

NOTE.—_The chemical nature of coloured substances has no influence upon the phenomena of simultaneous contrast._

71. The chemical nature of coloured bodies in juxtaposition has no influence upon the modifications of their colours. Whatever may happen to be the chemical composition of the coloured bodies, provided they be identical to the sight, they yield the same results. I need only cite the following examples:—Indigo, Prussian blue, cobalt, ultramarine, as nearly alike as possible, gave the same sort of modification; orange prepared from red lead, annotto, or a mixture of woad and madder, caused the same modification of the colours to which they were adjacent.

CHAPTER VII.

On the Juxtaposition of Coloured Bodies belonging to the Colours of the same Group of Coloured Rays.

72. Whenever there is a great difference between two contiguous colours, the difference becomes still more appreciable by putting the same colour successively in juxtaposition with the various colours belonging to the same group. For example, _orange and red_.

Orange being placed beside scarlet-red, pure red and crimson-red, it will be seen that the red acquires a purple and the orange a yellow tint.

Violet being placed beside scarlet-red, pure red and crimson-red, gives analogous results: the violet always appears bluer, and the red yellower or less purple.

73. These observations explain why we obtain results in accordance with the formula, even when such coloured substances are used as are far from exhibiting pure colours, namely, stained papers or stuffs.

74. The juxtaposition of coloured stripes is a means of demonstrating the difficulty of determining the types of pure colours by common pigments; at least, if we do not take into consideration the law of simultaneous contrast. For instance—

1. Place red in contact with orange-red; the first will appear purple and the second yellower, as above; but if the first red be placed beside purplish-red, the latter will appear bluish, and the former more yellow or orange; so that the same red will be purple in one case and orange in the other

2. Place yellow beside orange-yellow, the former will appear greenish and the latter redder; but if you put the first yellow beside a greenish-yellow, the last will appear greener, and the yellow more orange; so that the same yellow will incline to green in one case, and to orange in the other.

3. Place blue beside greenish-blue, the former will incline to violet, and the second will appear yellower. Put the same blue beside a violet-blue, the former will incline to green, and the second will appear redder; so that the same blue will be violet in one case and greenish in the other.

75. Hence we see that the colours which painters term simple—red, yellow, and blue—pass insensibly by juxtaposition into the condition of compound colours, since the same red is purple or orange; the same yellow is orange or green; and the same blue is green or violet.

CHAPTER VIII.

On the Application of the Law of Contrast to the Hypothesis that Red, Yellow, and Blue are the only Primary Colours; and that Orange, Green, Indigo, and Violet are Secondary or Composite Colours.

76. The experiments to which I have just applied the principle of the modification which colours undergo by juxtaposition, and the explanation consequent upon the manner in which white light has been considered, are also clearly explained in the language of painters and dyers, who admit of only three primary colours—red, yellow, and blue. As there are persons who, while they hold this opinion, desire, notwithstanding, to give a reason for the phenomena resulting from the juxtaposition of colours, I will explain them in accordance with this language; and, for greater clearness, I make five groups of juxtaposed colours, beginning with those which include the observations to which the preceding law is most easily applied. I shall presume that orange is composed of red and yellow, green of yellow and blue, indigo and violet of red and blue.

FIRST GROUP.—_Two Secondary Colours having a Simple Colour as a Common Element._

It is very easy to verify the law when we look at two colours which form part of the group: we see that by their reciprocal influence they lose more or less of the colour which is common to them. It is evident that they become more unlike each other in proportion to this loss.

1. _Orange and Green._—These colours having the element yellow in common, lose it by juxtaposition. _The orange appears redder, and the green bluer._

2. _Orange and Indigo._—These colours having the element red in common, lose it by juxtaposition. _The orange appears yellower, and the indigo greener._

3. _Orange and Violet._—Like the preceding.

4. _Green and Indigo._—These colours having the element blue in common, lose it by juxtaposition. _The orange appears yellower, and the indigo bluer._

5. _Green and Violet._—Like the preceding.

SECOND GROUP.—_A Compound Colour, and a Simple Colour, which is found in the Compound._

1. _Orange and Red._—The orange loses red, and appears yellower; the red becomes bluer, to differ as much as possible from the orange.

[Illustration: PLATE VI.]

2. _Violet and Red._—The violet loses red, and appears bluer; the red becomes yellower, to differ as much as possible from the violet.

3. _Indigo and Red._—Like the preceding.

4. _Orange and Yellow._—The orange loses yellow, and appears redder; the yellow becomes bluer, to differ as much as possible from the orange.

5. _Green and Yellow._—The green loses yellow, and appears bluer; the yellow becomes redder, to differ more from the green.

6. _Green and Blue._—The green loses blue, and appears yellower; the blue becomes redder, to differ as much as possible from the green.

7 _Violet and Blue._—The violet loses blue, and appears redder; the blue must become yellower to differ as much as possible from the violet.

8. _Indigo and Blue._—Like the two preceding.

THIRD GROUP.—_Two Simple Colours._ (See 6, 7.)

1. _Red and Yellow._—Red in losing yellow appears bluer; and the yellow losing red appears bluer; or, in other words, the red inclines to purple, and the yellow to green.

2. _Red and Blue._—The red in losing blue appears yellower; and the blue losing red appears yellower; or, in other words, the red inclines to orange, and the blue to green.

3. _Yellow and Blue._—The yellow in losing blue appears redder; and the blue losing yellow appears more violet; or, in other words, the yellow inclines to orange, and the blue to violet.

FOURTH GROUP.—_Two Compound Colours consisting of the same Simple Colours._

Indigo and Violet.—As indigo differs from violet only in containing more blue in proportion to red, it follows that the difference will be greatest when the indigo loses red and inclines to greenish blue, while the violet, by gaining red, inclines toward that colour. It is clear that, if the violet lost red, or if the indigo acquired it, the two colours would approximate; but, as they differ from each other, the first effect ensues.

We may further explain the preceding phenomena by considering indigo relatively to violet, as blue; then it will lose its blue, which is common to both colours, and incline to green; while the violet, also losing its blue, will appear redder.

FIFTH GROUP.—_A Compound Colour, and a Simple Colour, which is not found in the Compound._

1. _Orange and Blue._ 2. _Green and Orange._ 3. _Violet and Greenish Yellow._

Upon the hypothesis that orange, green, and violet are compound colours, and that red, blue, and yellow are simple, it follows that in opposing them in the order in which they are reciprocally complementary, and supposing also that the colours so juxtaposed are entirely free from any foreign colour, there appears no reason for the compound colour losing one of its elements rather than another, or for the simple colour being unlike one of the elementary colours rather than another. For instance, in the juxtaposition of green and red, we see no reason why green should pass into blue rather than into yellow, or why the red should incline to blue rather than to yellow.

SECTION II.

ON THE DISTINCTION BETWEEN SIMULTANEOUS, SUCCESSIVE, AND MIXED CONTRAST OF COLOURS, AND ON THE CONNEXION BETWEEN THE EXPERIMENTS MADE BY THE AUTHOR, AND THOSE PREVIOUSLY MADE BY OTHER

OBSERVERS. DISTINCTION BETWEEN SIMULTANEOUS, SUCCESSIVE, AND MIXED CONTRAST OF COLOURS.

77. Before speaking of the relation of my experiments to those made by others on the contrast of colours, we must distinguish three classes of contrast. The _first_ includes those relating to the contrast which I term _simultaneous_; the _second_ to that which I term _successive_; and the _third_ to that which I term _mixed_.

78. _Simultaneous contrast of colours_ includes that phenomena of modification which objects variously coloured seem to undergo in physical composition, and in the depth of tone of their respective colours, when seen at the same time.

79. _Successive contrast of colours_ includes the phenomena observed when the eyes having looked for some time at one or more coloured objects, perceive, after having ceased to look at them, images of those objects, presenting the colour complementary to that of the actual object.

80. This distinction also facilitates the understanding of the phenomena which maybe called _mixed contrast_; for, the retina having seen a certain colour for some time, has an aptitude to see for a further time the complementary of that colour, as well as any new colour presented by an external object; the sensation perceived being the result of this new colour, and the complementary of the first.

For want of this distinction, one of the branches of optics most fertile in applications, has not been treated with the clearness and precision which are necessary to show its importance to those who have not experimented upon it.

81. The following is a simple mode of observing _mixed contrast_:—Having closed one eye, the right for example, look steadily with the left at a sheet of paper of a colour A; when this colour seems to become dull, look immediately at a sheet of paper of the colour B, the eye then has the impression produced by the mixture of this colour B with the complementary (C) of the colour A.

82. To be convinced of this mixed sensation, it is only necessary to shut the left eye, and to look at the colour B with the right eye; when the sensation perceived is not only that of the colour B, but it may appear modified in the contrary way to that of the mixed sensation C + B, or what is the same, it appears to be rather A + B.

83. Upon shutting the right eye, and looking again at the colour B with the left eye, and that many times in succession, different sensations are successively perceived, but more and more feebly, until at length the left eye returns to its normal state.

84. I advise any person who thinks that one of his eyes is more able to perceive colours than the other, to look at a sheet of paper alternately with the right and left eye; if the sensations of each are identical, he may conclude that he has deceived himself. And even if the sensations be different, the experiment should be repeated several times, successively, for the difference observed in a single experiment might be occasioned by one of the eyes having been previously modified or fatigued.

85. This practice appears to me especially useful to painters. I now give some examples of mixed contrast.

86. The left eye, having looked for some time at red, has an aptitude to see afterwards green, the complementary of red. If then it be attracted by yellow, it perceives a sensation resulting from the mixture of green and yellow. The left eye being shut, and the right eye, which has not been modified by the sight of red, being opened, it sees yellow, and it is possible that this yellow may appear more orange than it is really.

87. _If the left eye_ | _and had_ | _the latter would_ _had first seen_ | _afterwards seen_ | _have seemed_ Yellow Red Violet. 88. Red Blue Greenish. 89. Blue Red Orange-red. 90. Yellow Blue Blue-violet. 91. Blue Yellow Orange-yellow. 92. Red Orange Yellow. 93. Orange Red Red-violet. 94. Red Violet Deep blue. 95. Violet Red Orange-red. 96. Yellow Orange Red. 97. Orange Yellow Greenish-yellow. 98. Yellow Green Bluish-green. 99. Green Yellow Orange-yellow. 100. Blue Green Yellow-green. 101. Green Blue Blue-violet. 102. Blue Violet Reddish-violet. 103. Violet Blue Greenish-blue. 104. Orange Green Bluish-green. 105. Green Orange Reddish-orange. 106. Orange Violet Bluish-violet. 107. Violet Orange Yellowish-orange. 108. Green Violet Red-violet. 109. Violet Green Yellow-green. 110. Red Green Bluer. 111. Green Red Tinted-violet. 112. Yellow Violet A little bluer. 113. Violet Yellow Greenish. 114. Blue Orange Yellower. 115. Orange Blue More violet.

116. I should observe that all these colours, at least to my eyes, did not undergo equally intense or equally continuous modifications. For instance, the modification produced by the successive view of yellow and violet, or of violet and yellow, is stronger and more durable than that produced by the successive view of blue and orange, and still more than that of orange and blue. The modification produced by the successive view of red and green, of green and red, is but slight, and not enduring.

I may also add that the depth of tone exercises some influence on the modification; for, if after looking at orange, we look at dark-blue, the latter will appear greenish rather than violet, a result contrary to that afforded by a light blue.

117. I have thought it the more necessary to mention under a special name the phenomenon which I call _mixed contrast_, as it explains certain facts remarked by dealers in coloured fabrics, as well as the inconvenience felt by painters, who, wishing to produce an exact imitation of their models, look at them so long as to be unable to perceive their tones and modifications. I will mention two facts which have been communicated to me by manufacturers, referring the reader to Part II. for the application of the study of mixed contrast to painting.

118. First Fact. When a purchaser has looked a long time at a yellow cloth, and he is then shown an orange, orange-red, or scarlet one, he finds it dull, and judges it to be a dark or crimson-red; because the retina affected by the yellow has a tendency to see violet; and hence all the yellow of the orange colour disappears, and the eye sees it as a red, or a red inclining to violet.

119. Second Fact. If there be presented to a purchaser, one after another, fourteen pieces of a red fabric, he judges the six or seven last pieces to be less beautiful than the first, although they may be all identical. What is the reason of this false judgment? It is, that the eyes which have seen six or eight red pieces in succession, are in the same condition as if they had looked steadily for the same length of time at a single red stuff,—having a tendency to see the complementary of red, that is green. This tendency necessarily enfeebles the brilliancy of the red of the last pieces. The dealer, therefore, that he may not be a sufferer from the fatigued eyes of his customer, after showing him a few red pieces, should present some green ones, to restore the eyes to their normal state. If the view of the green were sufficiently prolonged to pass the normal state, the eyes would acquire a tendency to see red, and then the pieces seen last would appear more beautiful than the rest.

PART THE SECOND.

ON THE APPLICATION OF THE LAW OF SIMULTANEOUS CONTRAST OF COLOURS.

INTRODUCTION.

120. Before entering into the details of these applications, I think it necessary to offer some considerations which will enable me to establish some propositions or principles, to which I shall have frequent occasion to refer. I propose to give—

121. 1. Definitions of several expressions applicable to colours and their modifications. 2. The means of representing and defining colours and their modifications by the aid of diagrams. 3. A classification of the harmonies of colours. 4. A view of some arrangements of the primary colours with white, black, and grey.

SECTION I.

Definition of the words Tones, Scales, and Hues.

122. The words _Tones_ and _Hues_ recur continually, both in common language and in that of artists; yet they are not so well defined as to be free from ambiguity, or to be well understood.

123. The word TONE of a colour will be employed exclusively to designate the various modifications which that colour, in its greatest intensity, is capable of receiving from white, which _lowers_ its tone, or of black, which _heightens_ it.

124. The word SCALE will be applied to the assemblage of tones of the same colour, thus modified. The pure colour is the normal tone of the scale, if the normal tone does not belong to a broken or reduced scale—_i.e._, to a scale, of which all the tones are made dull with black (149).

125. The word HUE will be applied exclusively to the modifications which a colour receives from the addition of a small quantity of another. We shall speak, for example, of the _tones_ of the blue scale, the _tones_ of the red scale, &c. We say the _hues_ of blue to designate all the scales whose colours, still remaining blue, yet differ from pure blue; each hue comprehending the tones which constitute a scale more or less allied to the blue scale.

126. I have defined the tones of a colour to be the various modifications, which that colour at its maximum of intensity is capable of receiving from black and white; it must be observed that the condition “maximum of intensity for receiving black,” is absolutely essential to this definition; for if black be added to a tone below the maximum, it would pass into another scale. Artists distinguish

colours as _pure, broken, reduced, grey_, or _dull_.

127. Pure colours are those termed _simple_, red, yellow, blue, and those which result from their binary compounds, orange, green, violet, and their _hues_. (150.) _Broken_ colours are the pure colours mixed with black, from the tone of the lightest to the deepest. According to these definitions, it is evident that in all the scales of simple and binary colours, the tones which are above the pure colour are _broken_ tones.

128. Artists, and especially painters and dyers, admit that the mixture of three primary colours, in a certain proportion, gives black; hence, when these three colours are so mixed that two predominate, black will result, formed from the union of the whole of the colour, which is in small quantity, within suitable proportions of the two predominant colours. For example, if blue be mixed with red and yellow, a little black is produced, which reduces or _breaks_ the orange.

129. We must remember that the _primary colours_ of painters are not those of the prismatic spectrum, but substances employed by them, as red, yellow, and blue colours.

SECTION II.

Of Diagrams designed to Represent and Define Colours and their Modifications.

130. Various contrivances have been proposed under the titles of Tables, Scales, Colour-Circles, Chromatometers, &c., for representing either by numbers or a rational nomenclature, colours and their modifications. They are generally founded on these three propositions:—1. There are three primary colours. 2. Equal portions of these colours being mixed, produce pure secondary colours. 3. Equal portions of the three primary colours produce black.

131. But we know of no substance which exhibits pure colour; that is, which reflects only one kind of coloured rays, whether pure red, pure yellow, or pure blue. And since it is impossible to procure pure colouring matters, how can it be said that orange, green, and violet are composed of two simple colours mixed in equal proportions? Or that black consists of a mixture of equal parts of three simple colours?

[Illustration: PLATE VII.]

These chromatic tables, &c., point out mixtures which do not produce the results deducible from the principles on which they are said to be based.

132. But most of the blue, red, and yellow colours with which we are acquainted, give, by their binary compounds, violet, green, and orange inferior in brilliancy to the natural violet, green and orange colours of objects. This result would be explained by admitting that colours mixed two by two, reflect at least two kinds of coloured rays; and that where there is any mixture of colours which reflect separately red, yellow, and blue, there is produced a certain amount of black which reduces the brilliancy of the mixture.

133. Conformably with this view, the violet, green, and orange colours which result from a mixture of coloured matters, are most brilliant when the respective colours of these materials approach each other. For example, a mixture of blue and red inclines more to violet than a mixture of blue and yellow inclines to green, and that of red and yellow inclines still more to orange.

134. In order to represent all the modifications that I have called _tones_ and _hues_ of colours, as well as the relations which exist between those that are complementary to each other, I have devised the following diagram (Plate 7). From a centre, _c_, I describe two circumferences, _y_ Y. I divide each of these by means of three rays, _c a_, _c b_, _c d_, into arcs of 120 degrees each. I divide the portion of each ray comprised between the two circles _y_ Y into twenty parts, which represent as many tones of the colours red, yellow, and blue.

135. In each of the scales of these three colours there is one tone, which, when pure, represents the colour of the scale to which it relates. I therefore call it the _normal tone of that scale_. If we represent a unit of surface _s_, entirely covered by the pigment which reflects the normal colour, and if we suppose that this colouring matter is equally distributed over the surface _a_ 1, we shall represent the tones superior to the normal tone by the unit of surface covered with 1 of the normal colour, plus the quantities of black increasing with the number of tones; and we shall represent the inferior tones by the unit of surface covered with a fraction of the quantity 1, constituting the normal tone, mixed with (——) quantities of black, as the tone has a less elevated number. If the tone 15 of the red scale be the normal tone, the normal tone of the yellow scale will have a lower number, while the normal tone of the blue scale will have a higher number. This depends upon the unequal lightness of the colours.

136. If each arc of 120° be divided into two of 60° and if radii pass through the points of division, beginning at _y_, there will be represented twenty tones of the orange, green, and violet scales, the colours at the extremities of each diameter being complementary to one another. Each arc of 60° might be divided into arcs of 30°, and thus would be obtained radii representing twenty tones of scales, which I shall call orange-red, orange-yellow, greenish-yellow, greenish-blue, bluish-violet, and violet-red.

137. By dividing each arc into five, for example, by means of five radii, which I divide into twenty parts each, beginning at the circumference _y_, I shall obtain sixty new scales.

138. Beginning with red, I designate them as follows:—

_a_ Red _e_ Yellow _i_ Blue 1 Red 1 Yellow 1 Blue 2 Red 2 Yellow 2 Blue 3 Red 3 Yellow 3 Blue 4 Red 4 Yellow 4 Blue 5 Red 5 Yellow 5 Blue 139. _b_ Red-orange _f_ Yellow-green _k_ Blue-violet 1 Red-orange 1 Yellow-green 1 Blue-violet 2 Red-orange 2 Yellow-green 2 Blue-violet 3 Red-orange 3 Yellow-green 3 Blue-violet 4 Red-orange 4 Yellow-green 4 Blue-violet 5 Red-orange 5 Yellow-green 5 Blue-violet 140. _c_ Orange _g_ Green _l_ Violet 1 Orange 1 Green 1 Violet 2 Orange 2 Green 2 Violet 3 Orange 3 Green 3 Violet 4 Orange 4 Green 4 Violet 5 Orange 5 Green 5 Violet 141. _d_ Orange-yellow _h_ Green-blue _m_ Violet-red 1 Orange-yellow 1 Green-blue 1 Violet-red 2 Orange-yellow 2 Green-blue 2 Violet-red 3 Orange-yellow 3 Green-blue 3 Violet-red 4 Orange-yellow 4 Green-blue 4 Violet-red 5 Orange-yellow 5 Green-blue 5 Violet-red

I attach no importance to this nomenclature; I employ it only as the simplest to distinguish the seventy-two scales just described. The number may be increased indefinitely, by inserting as many as we choose between the above.

142. Let us now represent the gradations of each colour in the scales of the circle by the addition to it of black, progressively increasing till it becomes pure black. Imagine a quadrant whose radius is equal to that of the circle, and arranged so as to turn upon an axis perpendicular to the plane of the circle. Divide this quadrant, 1st, by concentric arcs _y y■_, which coincide with the circles denoted by the same letters; 2nd, by ten radii, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10. Divide each of these radii into twenty parts, representing twenty tones, corresponding to the tones of the scales represented on the circle.

143. I suppose that the tenth radius comprises the gradations of normal black, covering the half-circle described by the movement of the quadrant upon its axis; this black mixed in decreasing quantities, with increasing quantities of white, gives the twenty tones of normal grey, and ends by being lost in the white situated above the tone 1. I suppose, further, that the normal tone of each of the scales taken upon each of the radii of the quadrant 1, 2, 3, 4, 5, 6, 7, 8, 9, is formed of the mixture of black with the colour of any of the scales that the circle contains, and in such a proportion that the normal tone 15 of that scale is represented by the unit of surface covered with 1, or ¹■/■■ of red.

144. The tone 15 of the scale of the

1st Radius = ■/■■ of Red + ¹/■■ of Black. 2nd ” = ■/■■ ” + ²/■■ ” 3rd ” = ■/■■ ” + ³/■■ ” 4th ” = ■/■■ ” + ■/■■ ” 5th ” = ■/■■ ” + ■/■■ ” 6th ” = ■/■■ ” + ■/■■ ” 7th ” = ³/■■ ” + ■/■■ ” 8th ” = ²/■■ ” + ■/■■ ” 9th ” = ¹/■■ ” + ■/■■ ”

These proportions relate to the effect of the mixtures upon the eye, and not to the material quantity of the red and black substances.

145. We see then—1. That each of these _tones_, 15, composed of colour and black, reduced by white and deepened by black, gives a scale of twenty tones, so much the more broken as they are nearer the scale of normal black. 2. That the quadrant by its movement upon the axis of the circle, represents the scales of every colour except red, broken by black. These broken scales are equidistant, and are formed of equidistant tones. 3. That all the colours are thus contained in a circle, whose plan comprehends the pure colours; the central space, black; and the intermediate space the pure colours, broken by the various proportions of black.

146. The diagram, as just described, thus represents the lowering of pure colours by white, and their gradation by black; their modifications by their mutual mixtures, the modification of hues, and the modification of breaking. We will presently inquire into the possibility of realizing it by means of coloured materials.

147. We have presumed—1. That the normal tone of each of the scales is as pure as possible. 2. That the tones bearing the same number in all the scales,—both those of the pure colours and those of the broken colours,—are, to the sight, of equal depth. 3. That if three tones, of the same number, be taken in three consecutive scales, the tone of the intermediate scale is the mean between the colours of the extreme scales. It is thus easy to explain the modifications of a pure colour commencing with its normal tone.

148. These modifications are so produced that—1. _The Pure Colour never leaves its Scale._—The modification is in the direction of the radius of the circle—proceeding from the normal tone towards the centre, it gains white; while proceeding from the normal tone towards the circumference, it gains black.

149. 2. _The Pure Colour leaves its Scale by the addition of Black._—In this case the various scales comprised in the quadrant perpendicular to the circle, begin at the normal tone of one of the pure scales of the circle with which the quadrant coincides. This normal tone, resulting from a quantity of colour represented by unity, covering a unit of surface _s_, the normal tones of the quadrant result from the mixture of black and a fraction of unity of the colour. These mixtures constitute broken colours, each covering a unit of surface _s_, and are of the same depth as the normal tone of the pure colour. The fraction of the quantity of colour is, in the broken normal tones, so much less, as the scales, to which these tones belong, approximate to the vertical axis of the semicircle.

Besides, each normal tone of the scales of the quadrant is modified, like the normal tones of the scales of the circle, by increasing quantities of white towards the centre, and of increasing quantities of black towards the circumference.

150. 3. _A Pure Colour is modified by the addition of another Pure Colour._—In this case hues are formed so much more resembling each other, as the quantities of the second colour are smaller. These modifications are made circularly, so that the tones retain their numbers. Thus admitting, with painters and dyers, that there are only three primary colours, and that by combining these two by two, we obtain all the pure complex colours; and by combining them in threes, all the broken colours; we find that it is possible to represent by this hypothesis, all the modifications of colours.

151. Another advantage of this construction is that of giving to all artists who may make applications of the law of simple contrast, the complementaries of all the pure colours; since the colours of the circular plan which are found at the extremities of the same diameter are complementary to each other. For example, not only are red and green, blue and orange, yellow and violet on the same diameter, but it is so with orange-red and bluish-green, and yellowish-green and violet-red; of red No. 1 and of green No. 1; so that all the colours opposed to each other are mutually complementary.

152. The complementary of a colour contiguous to another being once known, it is easy, according to the principles of combination, to determine the modification that the second must receive from the first; since this modification is the result of the mixture of the complementary with the contiguous colour. In fact, if there is no difficulty when the result is that of the non-complementary mixture with a simple colour, red, yellow, and blue, with a binary colour, orange, green, violet (using the language of painters, 76), there is no greater difficulty when the result is that of the mixture of two binary colours. For, the complementary being much less intense than the colour with which it is mixed, the result will be found by subtracting from the last binary colour the portion of its simple colour, which with the complementary forms white, or in other words, neutralises it.

153. _Examples._—1. Orange being added as a complementary to green, neutralises a portion of its blue, and consequently makes it appear less blue or more yellow.

2. Orange being added as complementary to violet, neutralises a portion of its blue, and consequently makes it appear less blue or more red.

3. Green being added as complementary to violet, neutralises a portion of its red, and consequently makes it appear less red or more blue.

154. These three examples are easily explained by subtracting from the binary colour a portion of its simple colour which is identical with that contiguous to it. Thus:—

1. Blue subtracted from Green, makes it appear more Yellow. 2. Blue ” ” Violet ” ” Red. 3. Red ” ” Violet ” ” Blue.

155. To put the diagram into practice we must adopt invariable types of colour, either in the solar spectrum, or in polarized light, or coloured rings, or colours developed in a constant manner, by any process whatever; then imitate them with the utmost fidelity, by means of colouring matters which should be applied to the circular plan of our chromatic diagram.

These types must be sufficiently numerous to reproduce the principal colours, in order that a practised eye may without difficulty insert all the tones of the same scale and all the hues of which types are wanting. In fact the diagram thus established, should present terms so near that the various colours of the natural bodies might be referred to them.

156. 1. _That it represents all the Modifications resulting from the Mixture of Colours._—Thus any colour lowered by white and deepened with black may, retaining its place in the scale, give rise to an infinite variety of tones; infinite, inasmuch as an unlimited number may be inserted from tone 1 to tone 20.

157. 2. Pure colours, by their mutual modifications, may produce an infinite variety of hues; for between two adjacent hues we may insert as many as we desire.

158. 3. The normal tone of a pure colour represented by a quantity equal to 1, covering the unit of surface, is the commencement of the normal tones and scales proceeding towards black; these normal tones being represented by black and a quantity of colour less than unity, constituting the mixtures which cover a unit of surface s, and colour it of a tone which has the same number as the normal tone of the pure scale to which it relates. It is understood that in proceeding from this tone to the corresponding tone of normal black, we may insert an unlimited number of mixtures of colour and black.

159. The modifications of colours, thus indicated by the diagram, render it extremely easy to understand the definitions given above (123) of the words, scales, tones, hues, pure and broken colours.

160. 2. _It affords the means of knowing the complementaries of every colour, since the names written at the two extremities of any one diameter indicate the colours complementary to each other._

161. EXAMPLES.—_a._ Suppose it be required to know the mutual influence of _blue and yellow_; at one extremity of a diameter we read the word _blue_, and at its opposite end, the word _orange_; showing that blue tends to give orange to yellow. Again, at the end of another diameter we read the word yellow, and at its opposite, the word violet; by which we see that yellow tends to give violet to blue.

162. _b._ Suppose _green and blue_ be contiguous; at one extremity of a diameter we read the word green, and at its opposite end, red; showing that green tending to give red to blue, must render it more violet. Again, at one end of a diameter we read the word blue, and at its opposite end, orange. But what arises from the mixture of green and orange? The orange will tend to neutralize its complementary, blue, in the green; and as it is always too feeble to neutralize all the blue, its influence will be limited to neutralizing a portion of it; whence it results that green, contiguous to blue, will appear more yellow than it really is.

163. _c._ Let _green and yellow_ be contiguous, we shall see in like manner that the green, by imparting red to the yellow, will render it orange; and that violet, the complementary of yellow, by neutralizing some yellow in the green, will make the green appear bluer, or less yellow.

164. 3. _A third advantage of this diagram, which distinguishes it from other chromatic diagrams, is, that it affords the preceding advantages, without being coloured._

165. 4. _A fourth advantage is that of its manifesting to all artists who use coloured materials of a definite size, especially the workers of tapestry, carpets and the like, the relation of number which must exist between the tones of the various scales which they work together._

SECTION III.

Harmony of Colours.

166. The eye has an undoubted pleasure in seeing colours, independently of the design and every other quality of the object which displays them. A suitable example to demonstrate this, is the wainscoting of an apartment in one or more flat tints which only attract the eyes and affect them more or less agreeably, as the colours are well or badly chosen.

167. First Case. _Agreeable Colour._—Every one, whose eyes are well organized, derives pleasure from looking at the coloured rays transmitted through a coloured glass, whether it be red, orange, yellow, green, blue, or violet.

168. Second Case. _Different Tones of the same Scale of Colour._—The simultaneous view of the series of tones of the same scale, which commences with white and ends with dark brown, gives undoubtedly an agreeable sensation, especially if the tones have equal and sufficiently numerous intervals; for example, from eighteen to thirty.

169. Third Case. _View of Different Colours, belonging to adjacent Scales, assorted conformably to Contrast._—The simultaneous view of different colours, belonging to scales more or less allied to each other, may be agreeable; but the assortment of scales

producing this effect is very difficult to obtain, because the more nearly the scales approach, the more frequently it happens that one of the colours injures that which is adjacent to it, and even both are reciprocally injurious. The painter may, however, take advantage of this harmony, by sacrificing one of the colours, which he subdues, to make the other more brilliant.

170. Fourth Case. _View of very different Colours, belonging to very distant Scales, arranged conformably to Contrast._—The simultaneous view of complementary colours, or of binary assemblages of colours, which, without being complementary, are yet very different, is also an undoubtedly agreeable sensation.

171. Fifth Case. _View of various Colours, assorted more or less according to the Law of Contrast_, being seen through a glass of a colour not deep enough to allow all the colours peculiar to the glass to be visible, afford a spectacle which is not without its charm, and which is placed between that produced by the tones of the same scale, and that which is produced by various colours; for it is evident, that if the glass were of a deeper colour, it would cause objects to be seen of the colour peculiar to it.

172. Hence we infer that there are six distinct harmonies of colour, comprised in two species.

FIRST SPECIES—HARMONIES OF ANALOGY.—1. _The harmony of scale_, produced by the simultaneous view of different tones of the same scale, more or less approximating. 2. _The harmony of hues_, produced by the simultaneous view of tones of the same, or nearly of the same depth, belonging to neighbouring scales. 3. _The harmony of a dominant coloured light_, produced by the simultaneous view of various colours assorted according to the law of contrast, but one of them predominating, as would result from the view of these colours through a slightly-coloured glass.

173. SECOND SPECIES—HARMONIES OF CONTRAST.—1. _The harmony of contrast of scale_, produced by the simultaneous view of two very distant tones of the same scale. 2. _The harmony of contrast of hues_, produced by the simultaneous view of tones of different depths, belonging, to neighbouring scales. 3. _The harmony of contrast of colours_, produced by the simultaneous view of colours, belonging to very distant scales, assorted according to the law of contrast. The difference in the depth of the adjacent tones may further augment the contrast of colours.

SECTION IV.

Assortments of Red, Orange, Yellow, Green, Blue, Violet with White, Black, and Grey.

174. It will not be useless to the object of this work to introduce some observations relative to the degree of beauty of certain arrangements of the primitive colours with black, white, and grey. But I cannot too strongly insist upon the fact, that they are not given as a rigorous deduction from scientific rules, for they are only the expression of my particular taste; yet I hope that many classes of artists, especially dressmakers, decorators of all kinds, designers of patterns for woven fabrics, paper-hangings, &c., will find advantage in consulting them.

175. The _ground_, as well as the interval between the colours, having influence upon their effect, all my observations were made with white, black, grey, and coloured circles, ■/■■ of an inch in diameter, separated by intervals of ■/■■ of an inch; thirteen circles arranged in a straight line forming a series.

176. The series designed to show the effect of white were on a ground of normal grey; those to show the effect of black and of grey were upon a white ground, slightly tinged with grey. It is necessary to remark that the _coloured_ circles placed apart, were upon black grounds, which must have exercised some influence.

177. The colours which have been under my notice are red, orange, yellow, green, blue, violet. Their differences in regard to brilliancy are so great as to admit of their being divided into two groups, one comprising red, orange, yellow, and bright green, the other blue and violet, which, with the same depth of tone, have not the brilliancy of the former. I shall call the first group _luminous colours_, and the second _sombre colours_. But the deep and broken tones of the _luminous scales_ may in many cases be assimilated to the sombre group, as the light tones of blue and violet may sometimes be employed as _luminous_ colours.

ARTICLE I.

Colours with White.

Plate 8.

A. _Binary Assortments._

178. All the primary colours gain by their juxtaposition with white, but the binary arrangements which result from them are not equally agreeable; and it is to be remarked that the depth of tone of a colour has a great influence upon the effect of its assortment with white.

The binary assortments in the order of their greatest beauty, are as follows:—_light blue_ and white, _rose_ and white, _deep yellow_ and white, _bright green_ and white, _violet_ and white, _orange_ and white.

Dark blue and dark red produce, with white, too strong a contrast of tone to allow of their assortment being as agreeable as that of their light tones. On the contrary, yellow being a light colour, we must take the normal or deepest tone of yellow to produce its most beautiful effect. Dark green and violet contrast too much in tone with white for their combination to be as agreeable as those which are made with the light tones of these colours. The objection which can be made to the combination of orange and white is that of too much brilliancy; yet I should not be surprised to find that many persons preferred it to that of violet and white.

B. _Tertiary Assortments of Colours complementary to each other with White._

179. It is to me impossible to establish an order of beauty among binary combinations of primary complementary colours. I shall therefore only describe the effect of white interposed between the binary complementary assortments, or between each of the complementary colours.

[Illustration: PLATE VIII.]

180. 1. _Red and Green_ are of all complementary colours the most equal in depth; for red, as regards its brilliancy, is midway between yellow and blue; and in green these two extremes are united. 2. The arrangement, white, red, green, white, &c., is not decidedly superior to the preceding, at least when the colours are not deep. 3. The arrangement white, red, white, green, white, &c., seems to me inferior to the preceding.

181. 1. _Blue and Orange_ are more opposed to each other than red and green, because the least brilliant colour blue, is separated, while the most brilliant are combined in orange. 2. The arrangement, _white, orange, blue, white_, &c., is agreeable. 3. The arrangement, _white, orange, white, blue, white_ &c., is also agreeable.

182. 1. _Yellow and Violet_ form an arrangement which, as regards depth of tone, is most distinct, since the least intense or lightest colour, the yellow, is separated from the others. Because of this great contrast of tone, the deep, but pure, greenish-yellow combines better with light violet, than light yellow and deep violet. 2. The arrangement, _white, yellow, violet, white_, &c., appears to me inferior to the preceding arrangement (1). 3. The arrangement, _white, yellow, white, violet, white_, &c., seems to me inferior to 2.

C. _Ternary Assortments of Colours not complementary with White._

183. 1. Red and orange do not accord well. 2. The arrangement, _white, red, orange, white_, &c., is scarcely preferable. 3. The arrangement, _white, red, white, orange, white_, &c., is not so bad as the preceding, because white being favourable to all the colours, its interposition between the colours which injure each other, can only produce an advantageous effect.

184. _Red and Yellow_ accord pretty well, especially if the red is purple-red rather than scarlet, and the yellow rather greenish than orange. 2, The arrangement, white, red, yellow, white, is preferable to the preceding. 3. The arrangement _white, red, white, yellow, white_, is still better.

185. 1. _Red and Blue_ accord passably, especially if the red incline rather to scarlet than to crimson. Deep tones are preferable to light ones. 2. The arrangement _white, red, blue, white_, &c., is preferable to 1. 3. The arrangement _white, red, white, blue, white_, is preferable to the second.

186. 1. _Red and Violet_ do not accord well, yet they are found in some natural productions, as the sweet pea. 2. The arrangement _white, red, violet, white_, is not so bad as the preceding. 3. The arrangement _white, red, white, violet, white_, is preferable.

187. 1. _Orange and Yellow_ accord incomparably better than red and orange. 2. The arrangement _white, orange, yellow, white_, is agreeable. 3. The arrangement _white, orange, white, yellow, white_, is not so good as 2, and perhaps 1, because there is too much white.

188. 1. _Orange and Green_ do not accord well. 2. The arrangement _white, orange, green, white_, is preferable to 1. 3. The arrangement _white, orange, white, green, white_, is perhaps preferable to 2.

189. 1. _Orange and Violet_ accord passably, yet not so well as orange and green; the contrast, in the latter case, is greater than in the arrangement orange and violet. 2. The arrangement _white, orange, violet, white_, &c., is preferable to the preceding. 3. The arrangement _white, orange, white, violet, white_, &c., is preferable to 2.

190. 1. _Yellow and Green_ form an agreeable combination. 2. The arrangement _white, yellow, green, white_, &c., is still more agreeable. 3. The arrangement _white, yellow, white, green, white_, &c., is inferior to the preceding, and perhaps to the first. The inferiority of 3 seems to me to be caused by too much light for the _green_.

191. 1. _Yellow and Blue._ The arrangement of _yellow_ and _blue_ is more agreeable than that of _yellow_ and _green_, but it is less lively. 2. The arrangement _white, yellow, blue, white_, &c., is perhaps preferable to the preceding. 3. The arrangement _white, yellow, white, blue_, &c., is perhaps inferior to the preceding.

192. 1. _Green and Blue_ produce an indifferent effect, but better when the colours are deep. 2. The arrangement _white, green, blue, white_, &c., is preferable. 3. The arrangement _white, green, white, blue, white_, &c., has a still better effect, because the light is more equally distributed.

193. 1. _Green and Violet_, especially when light, form a combination preferable to the preceding, _green_ and _blue_. 2. The arrangement _white, green, violet, white_, &c., is not decidedly superior to the preceding. 3. The arrangement, _white, green, white, violet, white_, &c., is not decidedly superior to it.

194. 1. _Blue and Violet_ accord badly. 2. The arrangement, _white, blue, violet, white_, &c. is scarcely preferable to the preceding (1). 3. The arrangement _white, blue, white, violet, white_, &c., is not so bad as the preceding (2).

ARTICLE II.

Colours and Black.

Plate 9. (Frontispiece.)

195. I do not know whether the use of black for mourning, prevents the use of it, in numberless cases, where it would produce excellent effects; it may be combined most advantageously, not only with sombre colours to produce the harmony of analogy, but also with light and brilliant colours to produce the harmony of contrast.

196. Chinese artists appear to have made excellent use of it, for I have often seen furniture, painting, ornaments, &c., where it has been most judiciously employed. I recommend those artists for whom this paragraph is particularly designed, to attend to the following observations, not doubting that many will be profitable to them.

A. _Binary Combinations._

197. No combination of primary colours with black is disagreeable, but there exists among these a generic difference of harmony, which is not shown, at least to nearly the same degree, in the binary combinations of white with the same colours. In fact the brilliancy of white is so predominant, that whatever may be the difference of lightness or brilliancy observed between the various associated colours, there will always be the harmony of contrast, according to what has been said (44-52) of the influence of white in raising the tone and augmenting the intensity of the colour adjacent to it.

198. If the binary combinations of black be examined in this point of view, it will be seen that the deep tones of all the scales, and even of the blue and violet scales (which are not, properly speaking, deep), form with it harmonies of analogy and not of contrast. So likewise do the unbroken tones of the _red, orange, yellow-green_ scales, and the very light tones of the violet and blue scale. We may add, according to what has been said (55), that the combinations of _black_ with sombre colours, such as _blue_ and _violet_, whose complementaries, orange and _greenish-yellow_, are luminous, may diminish the contrast of tone if the colours be juxtaposed with _black_ or one not far from it, and in this case the _black_ loses much of its vigour.

199. _Blue_ and _Black, Violet_ and _Black_, make combinations which may be employed successfully when only dark colours are required. The first is superior to the second.

200. Light combinations which exhibit the harmonies of contrast, appear to me in the order of beauty thus:—

Red or _Rose_ and _Black_, _Orange_ and _Black, Yellow_ and _Black_, lastly, _Bright Green_ and _Black_. As to yellow, I repeat that it must be brilliant and intense, inasmuch as black tends to impoverish its tone.

B.—_Ternary Combinations of Colours mutually Complementary with Black._

201. 1. _Red, Green_, &c. 2. _Black, Red, Green, Black_, &c. This arrangement being quite different from the former, it is difficult to decide respecting their comparative beauty. 3. _Black, Red, Black, Green, Black_, &c., appear to me inferior to the preceding, because there is too much black.

202. 1. _Blue, Orange_, &c. 2. _Black, Blue, Orange, Black_. I prefer the first to the second; the proportion of dark colour being too strong relatively to the _orange_. 3. _Black, Blue, Black, Orange, Black_, &c. This pleases me less than the first.

The effect of _black_ with _blue_ and _orange_ is inferior to that of _white_.

203. 1. _Yellow, Violet_, &c. 2. _Black, Yellow, Violet_, &c. 3. _Black, Yellow, Black, Violet, Black_, &c. The second is superior to the third, because the proportion of sombre colours with the _yellow_ is too strong in the latter. The first appears to me superior to the second.

C.—_Ternary Combinations of Colours not Complementary with Black._

204. 1. _Red, Orange_, &c. 2. _Black, Red, Orange, Black_, &c. 3. _Black, Red, Black, Orange, Black_, &c. As orange and red injure each other, there is an advantage in separating them by black. The third arrangement is preferable to the second; and both are preferable to those in which _black_ is replaced by _white_.

205. 1. _Red, Yellow_, &c. 2. _Black, Red, Yellow, Black_. 3. _Black, Red, Black, Yellow, Black_, &c. The two last arrangements appear to me superior to the first, and many persons would prefer them to the arrangement in which _white_ replaces _black_. I cannot too strongly recommend the arrangement 2 and 3 to artists, for whom these observations are especially designed.

206. 1. _Red, Blue_, &c. 2. _Black, Red, Blue, Black_. 3. _Black, Red, Black, Blue, Black_, &c. No. 2 is preferable to No. 3, because there are too many sombre colours in the latter, and because these differ too much from the _red_. The effect of _black_ upon the binary arrangement, _red_ and _blue_, is inferior to that of _white_.

207. 1. _Red, Violet_, &c. 2. _Black, Red, Violet, Black_, &c. 3. _Black, Red, Black, Violet, Black_, &c. The _red_ and _violet_ injure each other, it is therefore advantageous to separate them by _black_; but the latter does not produce so good an effect as _white_. It is difficult to say whether No. 3 is preferable to 2; because, if there be in the latter _red_ near _violet_, this defect is more than compensated in 3, by the predominance of sombre colours over the _red_.

208. 1. _Orange-Yellow_, &c. 2. _Black, Orange-Yellow_, &c. 3. _Black, Orange, Black, Yellow, Black_, &c. The _orange_ and _yellow_ being very luminous, the _black_ allies itself to them very well in the arrangement 2 and 3; and if the arrangement, _white, orange, yellow, white_, be preferred to No. 2, I think that in the arrangement 3, the _black_ produces a superior effect to the _white_.

209. 1. _Orange, Green_, &c. 2. _Black, Orange, Green_, &c. 3. _Black, Orange, Black, Green, Black_, &c. _Black_ combines well with _orange_, and with _bright green_. In like manner it combines well with _orange_ and _yellow_. If, in the arrangement 2, _white_ be preferred to _black_, I think it cannot be in 3. I recommend to artists the combination of _black_ with the binary arrangements _orange_ and _yellow, orange_ and _green_.

210. 1. _Orange, Violet_, &c. 2. _Black, Orange, Violet, Black_, &c. 3. _Black, Orange, Black, Violet, Black_, &c. _Black_ does not combine so well as _white_ with _orange_ and _violet_, because the proportion of dark colours relatively to _orange_, a very vivid colour, is too great.

211. 1. _Yellow, Bright Green_, &c. 2. _Black, Yellow, Green, Black_, &c. 3. _Black, Yellow, Black, Green, Black_, &c. _Yellow_ and _light green_ being luminous colours, _black_ combines very well with them; and if in the arrangement 2 the effect of _white_ be preferred to that of _black_, I think that it cannot be in the arrangement 3.

212. 1. _Yellow, Blue_, &c. 2. _Black, Yellow, Blue, Black_, &c. 3. _Black, Yellow, Black, Blue, Black_, &c. If the arrangement 2 be preferable to 3, I think it inferior to 1. The _black_ does not appear to combine so well as the white in the group _yellow_ and

blue.

213. 1. _Green, Blue_, &c. 2. _Black, Green, Blue, Black_, &c. 3. _Black, Green, Black, Blue, Black_, &c. Although _green_ and _blue_ do not well accord, yet the combination with _black_ is not decidedly advantageous. Because of the augmentation of the proportion of sombre colours, the _white_ has a superior effect to the _black_.

214. 1. _Green, Violet_, &c. 2. _Black, Green, Violet, Black_. 3. _Black, Green, Black, Violet, Black_, &c. If the _black_ unite better with _green_ and _violet_ than with _green_ and _blue_, yet these ternary combinations are inferior to the binary combinations; and inferior to the ternary combination where it is replaced by _white_.

215. 1. _Blue, Violet_, &c. 2. _Black, Blue, Violet, Black_, &c. 3. _Black, Blue, Black, Violet, Black_, &c.

216. Although _blue_ and _violet_ are colours which do not accord well, and although there is an advantage in separating them, yet it must be remembered that _black_ in isolating them, does not relieve their sombre colour, but, on the other hand, the harmony of the arrangements of 2 and 3 is more agreeable as a harmony of analogy than the harmony of contrast presented by _white_ with the same colours. Thus there are cases in which the assemblage of _black, blue_, and _violet_, may be advantageous, when it is desired to produce diversified, but not striking effects.

ARTICLE III.

Colours with Grey.

Plate 10.

[Illustration: PLATE X.]

217. All the primary colours gain purity and brilliancy by the proximity of grey; yet the effects are far from being like or even analogous to those which result from the proximity of the same colours with white. This will not create surprise, if it be remembered that while white preserves the character of each colour and exalts it by contrast, it can never be taken for a colour properly so called; grey, on the contrary, may be; it happens that the latter makes with the most sombre colours, as blue, violet, and deep tones in general, assortments which belong to the harmonies of analogy; while, with colours naturally brilliant, such as red, orange, yellow, and the light tones of green, they form analogies of contrast. But, although white contrasts more with sombre colours than with those that are naturally luminous, there is not observed between white and those two kinds of colours the difference observable between grey and the same colours. This result confirms what I have said of the binary combinations of black. (203.)

A.—_Binary Combinations._

218. _Grey and Blue, Grey and Violet_, form arrangements of which the harmony of analogy is agreeable, yet less so than that of _black_ with the same colours.

219. _Grey and Orange, Grey and Yellow_, _Grey and Bright Green_, form equally agreeable arrangements of harmony of contrast; perhaps they are less so than those in which _grey_ is replaced by _black_.

220. _Grey and Rose_ are a little dull and inferior to _Black and Rose_. All the binary arrangements of _grey_, except, perhaps, that of _orange_, are inferior to those of _white_.

B.—_Ternary Combinations of Complementary Colours with Grey_.

221. _Red_, _Green_, _&c_.—1. _Red, Green_, &c. 2. _Grey, Red, Green, Grey_, &c. 3. _Grey, Red, Grey, Green, Grey_, &c. If it be doubtful whether the binary assortment of _grey, red, and green_, be favourable, it cannot be called injurious. The third assortment is, perhaps, inferior to that in which the grey is replaced by _black_.

222. _Blue and Orange._—1. _Blue, Orange_, &c. 2. _Grey, Blue, Orange, Grey_. 3. _Grey, Blue, Grey, Orange, Grey_, &c. I prefer the first arrangement to the two others.

223. _Yellow and Violet._—1. _Yellow, Violet_, &c. 2. _Grey, Yellow, Violet, Grey_, &c. 3. _Grey, Yellow, Grey, Violet, Grey_, &c. Although the arrangements 2 and 3 are lighter than the arrangements in which _grey_ is replaced by _black_, yet the binary arrangement appears to me preferable to the ternary.

C.—_Ternary Assortments of Colours not Complementary to each other with Grey._

224. _Red and Orange._—1. _Red, Orange_, &c. 2. _Grey, Red, Orange, Grey_, &c. 3. _Grey, Red, Grey, Orange, Grey_, &c. The arrangements 2 and 3 are preferable to the binary. The third is preferable to the second. In short, the grey produces, with _red_ and _orange_, a better effect than _white_, but the effect is inferior to that of _black_.

225. _Red and Yellow._—1. _Red, Yellow_, &c. 2. _Grey, Red, Yellow, Green_, &c. 3. _Grey, Red, Grey, Yellow, Grey_, &c. Although the grey combines well with the _red_ and the _yellow_, it has not so decidedly advantageous an effect as _black_ in the binary arrangement.

226. _Red and Blue._—1. _Red, Blue_, &c. 2. _Grey, Red, Blue, Grey_, &c. 3. _Grey, Red, Grey, Blue, Grey_, &c. The arrangement 2 is preferable to 3. I dare not say to 1. The effect of grey is inferior to that of _white_.

227. _Red and Violet._—1. _Red, Violet_, &c. 2. _Grey, Red, Violet, Grey_, &c. 3. _Grey, Red, Grey, Violet, Grey_, &c. The assortment 3 appears to me superior to 2, and the second to the first; but it is difficult to say whether _grey_ is superior to _black_. I am certain it is superior to _white_.

228. _Orange and Yellow._—1. _Orange, Yellow_, &c. 2. _Grey, Orange, Yellow, Grey_, &c. 3. _Grey, Orange, Grey, Yellow, Grey_, &c. The assortment 3 appears to me preferable to 2; the harmony of contrast is less intense than with _black_. The assortment 3 is, perhaps, superior to the assortment of _white, orange, white, yellow, white_.

229. _Orange and Green._—1. _Orange, Green_, &c. 2. _Grey, Orange, Green, Grey_, &c. 3. _Grey, Orange, Grey, Green, Grey_, &c. Grey combines well with _orange_ and _green_, but it does not contrast so agreeably as _black_ or _white_.

230. _Orange and Violet._—1. _Orange, Violet_, &c. 2. _Grey, Orange, Violet, Grey_, &c. 3. _Grey, Orange, Grey, Violet, Grey_, &c. The binary assortment appears to me preferable to the other two. The assortment 2 is preferable to 3. If the _grey_ is a little dull with _orange_ and _violet_, it has not the same disadvantage as _black_, in causing too great a predominance of sombre colour.

231. _Yellow and Green._—1. _Yellow, Green_, &c. 2. _Grey, Yellow, Green, Grey_, &c. 3. _Grey, Yellow, Grey, Green, Grey_, &c. _Grey_ combines well with _yellow_ and _green_, but the assortments 2 and 3 are a little dull, and inferior to those in which _black_ replaces _grey_.

232. _Yellow and Blue._—1. _Yellow, Blue_, &c. 2. _Grey, Yellow, Blue, Grey_, &c. 3. _Grey, Yellow, Grey, Blue, Grey_, &c. The two assortments, two and three, are inferior to the first. The _grey_ is heavy to _yellow_ and _blue_; its effect is inferior to that of _white_, and perhaps also to that of _black_.

233. _Green and Blue._—1. _Green, Blue_, &c. 2. _Grey, Green, Blue, Grey_, &c. 3. _Grey, Green, Grey, Blue, Grey_, &c. _Grey_, in its combination with _green_ and _blue_, has not the same objection as _black_, but it has an inferior effect to _white_.

234. _Green and Violet._—1. _Green, Violet_, &c. 2. _Grey, Green, Violet, Grey_, &c. 3. _Grey, Green, Grey, Violet, Grey_, &c. _Grey_ is not employed advantageously with _green_ and _violet_, it is inferior to _white_ in the ternary arrangements, and perhaps I should also give preference to _black_.

235. _Blue and Violet._—1. _Blue, Violet_, &c. 2. _Grey, Blue, Violet, Grey_, &c. 3. _Grey, Blue, Grey, Violet, Grey_, &c. The remarks made (218) in the assortment of _black_ with _blue_ and _violet_ are applicable to the arrangement with grey, taking into account the difference of tone which exists between _grey_ and _black_.

Recapitulation.

236. I will now give a summary of the observations which appear the most striking on reading the foregoing paragraphs, premising, however, that I do not pretend to establish laws fixed upon scientific principles, but to state general propositions which express my own peculiar taste.

237. 1st. _In the harmony of contrast the complementary arrangement is superior to every other._

The tones must be as nearly as possible of the same depth to produce the finest effect. The complementary arrangement in which white associates most advantageously, is that of blue and orange, and that of yellow and violet is the least advantageous.

238. 2nd. _The Primaries, Red, Yellow, and Blue associated in pairs assort better together, as a harmony of contrast, than an arrangement formed of one of these primaries, and of a binary colour in juxtaposition with it, having the same primary as one of its elements._

Examples.

Red and Yellow accord better than Red and Orange. Red and Blue " " Red and Violet. Yellow and Red " " Yellow and Orange. Yellow and Blue " " Yellow and Green. Blue and Red " " Blue and Violet. Blue and Yellow " " Blue and Green.

239. 3rd. _The arrangement of Red, Yellow, or Blue with a binary colour containing the former, contrasts the better, as the simple colour is essentially more luminous than the binary._

Whence it follows, that in this arrangement, it is an advantage for the red, yellow, or blue to be of lower tone than the binary colour.

Examples.

Red and Violet accord better than Blue and Violet. Yellow and Orange " " Red and Orange. Yellow and Green " " Blue and Green.

240. 4th. _When two colours accord badly together, it is always advantageous to separate them by White._

In this case it is more advantageous to place each colour next to white, than in an assortment where the two colours are together beside white.

241. 5th. _Black never produces a bad effect when it is associated with two luminous colours. It is therefore often preferable to White, especially in an assortment where it separates the colours from each other._

Examples.

1. Red and Orange.

Black is preferable to white in the arrangements 2 and 3 of these two colours. 2. Red and Yellow. 3. Orange and Yellow. 4. Orange and Green. 5. Yellow and Green.

Black, with all these binary assortments, produces harmony of contrast.

242. 6th. _Black in combination with sombre colours, such as blue and violet, and with broken tones of luminous colours, produces harmony of analogy, which, in many instances, may have a good effect._

The harmony of analogy of black, associated with blue and violet, is preferable to the harmony of contrast of the assortment white, blue, violet, white, &c., the latter being too crude.

243. 7th. _Black does not accord so well with two colours, one of which is luminous, the other sombre, as when it is associated with two luminous colours. In the first instance the combination is so much the less agreeable as the luminous colour is more brilliant._

With all the following assortments Black is inferior to White. 1. Red and Blue. 2. Red and Violet. 3. Orange and Blue. 4. Orange and Violet. 5. Yellow and Blue. 6. Green and Blue. 7. Green and Violet.

With the assortment yellow and violet, if it is not inferior to white, it produces only a mediocre effect.

244. 8th. _Although Grey never produces exactly a bad effect in its association with two luminous colours, yet in most cases its assortments are dull, and it is inferior to Black and White_.

Among the assortments of two luminous colours, there are scarcely any besides those of red and orange with which grey associates more happily than white. But it is inferior to it, as also to black, in the arrangements red and green, red and yellow, orange and yellow, orange and green, yellow and green. It is also inferior to white, with yellow and blue.

245. 9th. _Grey, in combining with sombre colours, such as Blue and Violet, and with broken tones of luminous colours, produces harmonies of analogy, which have not the vigour of those with black; although the colours do not combine well together, it has the advantage of separating them from each other._

246. 10th. _When Grey is associated with two colours, one of which is luminous the other sombre, it will perhaps be more advantageous than White, if this produces too strong a contrast of tone; on the other hand, it may be more advantageous than Black, if that increases too much the proportion of sombre colours._

Examples.

Grey associates better than Black with—

1. Orange and Violet. 2. Green and Blue. 3. Green and Violet.

247. 11th. If, when two colours accord badly, there is in principle an advantage in separating them by White, Black, or Grey, it is important to the effect to take into consideration—1. The height of tone of the colours. 2. The proportion of sombre to luminous colours, including, in the first, the broken brown tone of the brilliant scales, and in the luminous colours, the light tones of the Blue and Violet scales.

Consider the height of tone of the colours.

248. The effect of white with red and orange is inferior as their tones become higher, especially in the assortment white, red, orange, white, &c.; the effects of the white being too crude. On the contrary, black unites very well with the normal tones of the same colours, that is to say, the highest tones without any mixture of black. Although grey does not associate so well as black with red and orange, it has the advantage of producing a less crude effect than white.

Consider the proportion of sombre to luminous colours.

249. Whenever colours differ very much, either in tone or in brilliancy, from the black or white with which we wish to associate them, that arrangement where each of the two colours is separated from the other by black or white, is preferable to that in which the black or the white separate each pair of colours. Thus the assortment white, blue, white, violet, white, &c., is preferable to the assortment white, blue, violet, white, &c., because the separation of the brilliant from the sombre is more equal in the first than in the second. I should add that this is somewhat more symmetrical as to the position of the two colours, and the principle of symmetry influences our judgment of things more than is generally recognised. It is also in conformity with the above, that the assortment black, red, black, orange, black, &c., is preferable to the assortment black, red, orange, black, &c.

250. Some remarks appear to me also necessary to prevent false deductions from the above propositions. In the preceding examples, the colours, including white, black, and grey, are supposed to occupy an equal extent of surface, and to be placed at equal distances apart, for without these conditions the results will be different; for example, I have preferred the assortment white, red, white, yellow, white, to the assortment white, red, yellow, white. There are some cases in which the latter is preferable to the former, as in the arrangement of flowers in gardens, especially yellow and rose flowers, which present less coloured surface than the white flowers with which they are associated.

251. I have spoken of the good effects of black and green separated, and I may add that green designs upon a black ground are also agreeable; but it does not follow that black lace upon a green stuff will have a good effect, at least on the optical quality of black, for this acquires a rusty tint, which resembles a faded colour.

252. The more colours are opposed, the easier it is to assort them; because they do not experience by their mutual juxtaposition, any modification which renders them disagreeable, as generally happens to colours which are very nearly alike. Must we then conclude that with two colours which have in this case been indicated to an artist to be employed, with some liberty to modify them, he should endeavour to increase the effect of contrast rather than that of analogy? Certainly not; for frequently the latter is preferable to the former. For example:—Take orange-red and a pure red, instead of increasing the yellow in the orange-red, or of giving a violet hue to the red, it sometimes will be preferable to incline towards the harmony of scale or of hue, by endeavouring to make the orange one of the light tones of a scale whose red will be brown.

253. In conformity with this manner of observing, when we would avoid the bad effect of two adjacent colours by white, black, or grey, we must see whether, instead of a harmony of contrast, it may not be better to obtain the harmony of analogy.

254. Finally, when we bring into combination not normal grey, but a coloured grey, we are always sure of obtaining an effective harmony of contrast by taking a grey coloured with a complementary of that opposed to it. Thus an orange-grey or carmelite-brown or maroon has a good effect with light blue.

FIRST DIVISION.—IMITATION OF COLOURED OBJECTS WITH COLOURED MATERIALS IN A STATE OF INFINITE DIVISION.

INTRODUCTION.

255. Coloured materials, such as Prussian blue, chrome-yellow, vermilion, &c., are infinitely divided, so to speak, either when ground pure, or mixed with a white material, in a gummy or oily liquid.

The reproduction of the images of coloured objects with these pigments is called the _Art of Painting_.

256. There are two systems of Painting—the one consists in representing as accurately as possible upon a flat surface an object in relief in such a way that the image makes an impression upon the eye of the spectator similar to that which the object itself would produce. This is termed the _Art of Chiaro-'scuro_.

257. There is a means of imitating coloured objects much simpler in its facility of execution than the preceding. It consists in tracing the outline of the different parts of the model, and in colouring them uniformly with their peculiar colours. There is no relief, no projection; it is the plane image of the object, since all the parts receive a uniform tint: this system of imitating is _Painting in Flat Tints_.

PAINTING ON THE SYSTEM OF CHIARO-'SCURO.

258. Are the modifications perceived in a single coloured object, for example, in a blue or red stuff, &c., indeterminable, when these draperies are seen as draperies of a vestment or furniture, with more or less distinct folds, or are they determinable, in given circumstances? This is a question of which I am about to attempt a solution.

259. Firstly, let us distinguish three circumstances in which modifications of colours may be observed:—

1. Modifications produced by coloured lights falling upon the model.

2. Modifications produced by two different lights—as, for example, the light of the sun and diffused daylight—each illuminating different parts of the same object.

3. Modifications produced by diffused daylight.

260. We will suppose that in the two first cases the lighted surfaces are plane, and that all their superficial parts are homogeneous, and in the same conditions, except that of light. In the third case, we shall consider the position of the spectator viewing an object lighted by diffused daylight, the surface of which is not so disposed as to act equally in all its parts upon the light which it reflects to the eye of the spectator.

261. Modifications produced by coloured lights.

Red rays falling on Black make it appear Purple-black. ” White ” Red. ” Red ” Redder. ” Orange ” Redder. ” Yellow ” Orange. ” Deep Green ” Red-black. ” Light Green ” Reddish-grey. ” Light Blue ” Violet. ” Violet ” Purple.

262. Modifications produced by Orange light.

Orange rays falling on— Black make it appear Maroon, or Carmelite-brown. White ” Orange. Orange ” More vivid. Red ” Scarlet. Yellow ” Yellow-orange. Light Green ” Yellow-green. Deep Green ” Rusty-green. Light Blue ” Orange-grey. Deep Blue ” Grey, slightly Orange-grey. Indigo Blue ” Orange-maroon. Violet ” Red-maroon.

263. Modifications produced by Yellow light.

Yellow rays falling on— Black make it appear Yellow-olive. White ” Light Yellow. Yellow ” Orange-yellow. Red ” Orange. Orange ” Yellower. Green ” Greenish-yellow. Light Blue ” Yellow-green. Deep Blue ” Green-slate. Indigo ” Orange-yellow. Violet ” Yellow-maroon.

264. Modifications produced by Green light.

Green rays falling on— Black make it appear Greenish-brown. White ” Green. Green ” More intense and brilliant. Red ” Brown. Orange ” Faint Yellow, a little Green. Green ” Greener, according to its depth. Indigo ” Dull Green. Violet ” Bluish-green Brown.

265. Modifications produced by Blue light.

Blue rays falling on Black make it appear Blue-black. Black ” White ” Blue. ” ” Blue ” More vivid. ” ” Red ” Violet. { Brown, having a ” ” Orange ” { pale tint of Violet. Blue ” Yellow ” Green. ” ” Green ” Blue-green. ” ” Indigo ” Dark-blue Indigo. ” ” Violet ” Dark-blue Violet.

266. Modifications produced by Violet light.

{Very faint Violet rays falling on Black make it appear {Violet-black. ” ” White ” Violet. ” ” Violet ” Deeper Violet. {Red-violet ” ” Red ” {Purple. ” ” Orange ” Light Red. {Brown, with a ” ” Yellow ” {very slight tint {of Red. ” ” Green ” Light Purple. {Fine Blue ” ” Blue ” {Violet. {Deep Blue ” ” Indigo ” {Violet.

267. It is understood that to represent the preceding phenomena exactly, we must take into account the facility with which coloured light penetrates every kind of glass, the more or less intense colour of the stuff, and the kind of scale to which the coloured stuff and that of the transmitted coloured light respectively belong.

268. These observations were made by partially exposing coloured stuffs to the sun’s rays transmitted through coloured glasses. The portion of stuff not exposed to these rays, was lighted by the direct light of the sun. The portion of stuff which received the action of the coloured rays being exposed to diffused daylight, reflected also rays of that light which it would have reflected in case it had been protected from the influence of the rays transmitted to it through coloured glasses.

269. II. Modifications produced by two lights of different intensity.

270. 1. The modification by the light of the sun falling upon one part of the surface of a coloured body, while the other part is enlightened by diffused daylight.

2. The modification produced when two parts of the same object are unequally illuminated by diffused daylight.

An object lighted partly by the sun, and partly by diffused daylight.

271. To observe this kind of modification properly, let us expose to the sun a square piece of stuff A B, two and a half inches broad (Plate I., fig 4) and place in the middle a piece of black wire _f, f■_; then put parallel to this, and in the middle between A and B, two wires _e, e■_ and _g, g■_, of about three-tenths of an inch in width. The extremity _g■_ is fixed upon a perpendicular plane, so high, that all the part B _f, f■_ may be in shadow.

272. 1. _If the stuff is red_, the lighted portion A is more orange or less blue than the part B, which is in shade; and the portion _a_ is more orange than the portion _a■_, as the portion _b_ is bluer than the portion _b■_.

273. 2. _If the stuff is orange_, A is more orange or less grey than B; and the portion _a_ is deeper, more vivid than _a■_, as _b_ is more grey and duller than _b■_.

274. 3. _If the stuff is yellow_, A is more vivid, more orange than B; _a_ is more so than _a■_, as _b_ is duller than _b■_.

275. 4. _If the stuff is green_, A is less blue or more yellow than B; and _a_ is of a yellower green than _a■_, as _b_ is bluer than _b■_.

276. 5. _If the stuff is blue_, A is less violet and more green than B; and _a_ is greener than _a■_, as _b_ is more violet or less green than _b■_.

277. 6. _If the stuff is indigo_, A is redder or less blue than B; and _a_ is redder than _a■_, as _b_ is deeper or bluer than _b■_.

278. 7. If the stuff is violet, A is less blue than B; and _a_ is redder than _a■_ as _b_ is bluer than _b■_.

279. 2nd. Two contiguous parts of the same object unequally illuminated by the same light, when viewed simultaneously, differ from each other, not only in depth of tone, but also in optical composition of colour.

Place half-a-sheet of coloured paper (Plate I., fig. 5) upon the partition _b_, of a chamber receiving diffused daylight by a window _f_: place another half-sheet upon the partition _a_, in such a manner that it will be lighted directly by the diffused light, while the other is only indirectly lighted by reflection from the walls, floor, and ceiling: the diffused light thus reflected being only white light, then stand at _c_, so as to see both half-sheets at once. I shall designate that which is upon the partition _a_, and most lighted, by A, and the other, which is upon the partition _b_, and less lighted, by B.

These letters in the plate indicate the respective positions of the half-sheets.

280. The inference from these observations is, that the colour of the same body varies, not only in intensity of tone, but also of hue, according as it is lighted directly by the sun, by diffused daylight, or by diffused reflected light. This result must never be overlooked whenever we define the colours of material objects.

3rd. _Modifications produced by diffused daylight reflected by a surface all the parts of which are not in the same position relatively to the eye of the spectator._

281. Distant bodies are rendered perceptible to the eye only in proportion as they radiate or reflect, or transmit the light which acts upon the retina.

According to the laws of reflection, it happens that those portions of a surface which are in relief, or hollow, must reflect the light in such a manner, that the eye of the spectator, in a given position, will see these parts very variously lighted, in respect to the intensity of reflected light, so that the parts of this surface will be, relatively to the eye, in the same condition as the homogeneous parts of a plane surface, which are illuminated by lights of unequal intensity.

There will be this difference, however, that the parts of the surface of a body which appears to us hollow, and especially in relief, being but feebly varied in the greater number of contiguous parts, there will be generally a gradual diminution of the effects observed in the case in which we have studied the modifications of two plane homogeneous surfaces, lighted by diffused lights of unequal intensity. The sphere presents a remarkable example of the manner in which light is distributed over a convex surface, relatively to the eye of an observer, who views it from a given position.

282. I shall not occupy myself with this gradation of white light, from parts illuminated to those which do not appear so. I regard only the principal modifications, and take for examples the cases where they are as evident as possible. These modifications can be reduced to the four following:—

First modification, produced by the maximum of white light which the surface of a coloured body is capable of reflecting.

283. Other things being equal, the more highly the surface of a body is polished, the more it will reflect white and coloured light. If we observe the surface of a stick of sealing-wax, suitably placed, we shall perceive a white stripe parallel to the axis of the cylinder, produced by so large a quantity of colourless reflected light that the red light reflected from this stripe is not appreciable by the eye. Thus the white light reflected by a coloured body may be of sufficient intensity to render the colour of the body in some of its parts imperceptible.

Second modification, produced by those parts of a coloured surface which send to the eye, in proportion to the coloured light, less white light than the other parts differently lighted, or differently placed in relation to the spectator.

284. When the eye sees certain parts of the surface of a polished or uniformly coloured object which reflects to it proportionally to the coloured light less of white light than the other parts, the first parts will appear in most cases of a more intense tone of colour than the second. We will cite the following:—

Example 1.—A cylinder of red sealing-wax presents, proceeding from the white stripe mentioned above, a red colour deeper in proportion as less white light reaches the eye. Thus, in a certain position where the white stripe appears to be in the middle of the cylinder, the part most lighted will appear coloured, reflecting a red inclining to scarlet, while that which is the least lighted reflects a red inclining to crimson.

Example 2.—If the eye is directed into a gold vase of sufficient depth, the gold does not appear yellow as on the exterior surface, but of a red-orange; because less white light, in proportion to coloured light, reaches the eye in the first case than in the second. It is for this reason that the concave parts of gold ornaments appear redder than the convex.

Example 3.—The spiral thread of a piece of twisted silk or wool held perpendicularly before the eye, appears in the part opposite to the light, of a much more decided colour than on the rest of the surface.

Example 4.—The folds of bright draperies present the same modification to an eye properly placed; the effect is particularly remarkable in yellow silk stuffs, and in sky-blue; for we can easily understand that it is less marked when the stuffs are less bright and of dark colours.

Example 5.—There are some stuffs which appear to be of two tones of the same scale of colour, and sometimes also of two tones of two contiguous scales, although the weft and the warp of these stuffs are of the same tone and the same colour. The cause of this appearance is very simple; the threads which, parallel to each other, form the designs, are in a different direction to the threads which constitute the ground of the stuff. Hence, whatever may be the position of the spectator with regard to the stuff, the threads of the design will always reflect coloured and white light in a different proportion to that reflected by the threads of the ground, and, according to the position of a spectator, the design will appear to be lighter or darker than the ground.

Third modification.—The colour complementary to that of a coloured object developed in one of its parts, in consequence of simultaneous contrast.

285. A natural consequence of the law of simultaneous contrast in general, and of the effect of a colour upon grey and black in particular, is, that since the same object presents some parts more or less dark, contiguous to some parts where we see the colour peculiar to the object, the first parts will appear tinted with the complementary to this colour. But to observe this effect, it is necessary that the grey part should reflect to the eye white light, and little or none of the coloured light which the object naturally reflects.

Fourth modification, in a single coloured stuff.

286. For example, if the eye is directed towards a window which admits daylight, and a person clothed in a new blue coat, dyed with indigo or Prussian blue, be at the window, the eye will see one part of the coat will appear different from the other part, because the nap of the cloth is disposed in a contrary direction; one being of a fine blue, while the other is of an orange-grey, by the effect of contrast of the blue part with a part that reflects very little white light to the eye, without, or almost without, blue light.

287. But as the pile of the nap loses its regular position by wear, the cloth becoming dull and soiled, the coloured light is reflected irregularly from all points; and the effect is either absolutely destroyed or much weakened.

If the garment be of a deep green, the grey part will appear reddish; if it be of a violet, maroon, or claret, the grey part will appear yellow.

288. The complementary is only developed upon cloths of dark and sombre colours; thus red, scarlet, orange, yellow, and light blue garments do not exhibit it, because they have always too much of the essential colour which is reflected. The modification occurs only when one of the parts is more strongly illuminated than the other by diffused light (279).

289. There is also one circumstance where the fourth modification will appear evident; it is when we look at a series of light tones—blues, rose, &c. (belonging to the same scale)—of a skein of silk or wool, placed upon an easel, that one-half of the same skein presents to the eye the threads disposed in a contrary direction to those of the other half. The half of the skein which does not reflect coloured light to the eye, appears tinted with the complementary of the other half which does reflect it.

290. Fourth modification in a stuff presenting a dark and a light tone belonging to the same scale.

If we place in juxtaposition a dark tone and a light tone of the same scale, well assorted, the light tone will appear of the colour complementary to the scale to which it belongs. This modification is too important to allow me to pass it over hastily.

291. When we look for several seconds on a fabric dyed with a coloured ground, and on which therefore patterns intended to be white, but which, owing to the imperfection of the process employed, have received a light tone of the colour of the ground, the patterns will appear of the colour complementary to the latter. Thus, upon a ground of yellow-chromate of lead, they will appear violet; upon a ground of orange-chrome, they will appear blue; upon a green ground, rose, &c. To dispel the illusion, and to recognise the true tint of the pattern, it is only necessary to cover the ground with a white paper so perforated as to leave visible only the pattern coloured like the ground. The influence of a dark tone upon a feeble tone is such, that not only is the latter neutralized, but the place it occupies upon the cloth appears also tinted with its complementary colour.

292. From the preceding observations it follows that there may be a printed cotton, the design of which, although coloured, will appear to most eyes white, and not of the complementary of the ground. For those eyes which see it thus, the perception of the phenomenon of contrast will correct the imperfection of the art of the calico-printer.

293. In the Lectures upon Contrast, which I delivered in 1836, at the Gobelins, I remarked, that in applying paper (cut for the purpose) upon the lights of a blue drapery of the Virgin in a tapestry representing the Holy Family, after Raphael, they appeared of

a light blue, although, when they were seen surrounded with darker tones, they appeared of an orange tint.

294. We can conceive without difficulty that if the modification is not manifested with monochromous objects of vivid colours, as yellow, scarlet, &c., it is because that part of the surface of these objects which reflects the least light to the eye, always reflects enough of its peculiar colour to neutralize the complementary which the coloured light of the illuminated portion tends to develop. I believe that this effect tends to enfeeble the coloured light of the shaded part.

295. Although, in this chapter, I do not propose to treat of the modifications shown by coloured stuffs with white designs; yet, as it is a case so connected with the preceding considerations, I cannot avoid mentioning them in this place.

296. If we observe a sky-blue silk with white flowers, the weft of which is in an opposite direction to the weft of the blue ground, we shall see the flowers white, if they are placed in the most favourable manner to receive the white light reflected by them; while, in the contrary position, we shall see these flowers absolutely orange. There is still much white light reflected, but it is not sufficiently vivid to neutralize the development of the complementary of the ground.

PAINTING ON THE SYSTEM OF FLAT TINTS.

297. In painting by flat tints, the colours are neither shaded, blended together, nor modified by the coloured rays coming from the surrounding parts of the picture.

In pictures which belong to this kind of painting, the representation of the model is reduced to the observance of linear perspective, to the employment of vivid colours in the nearer parts, and of pale and grey colours in the more distant.

If the choice of contiguous colours has been made conformably to the law of simultaneous contrast, the effect of the colour will be greater than if it had been painted on the system of chiaro-'scuro.

298. In every instance where painting is an accessory, and not a principal feature, painting in flat tints is in every respect preferable to the other kind.

299. The essential qualities of painting in flat tints necessarily reside in the good choice of colours and well drawn outlines. These outlines contribute to render the impressions of colours stronger and more agreeable, when, circumscribing forms clothed in colours, they concur with them in suggesting to the mind a graceful object, when even the imitation of it does not give a faithful representation.

300. We may, in conformity with what has been said, consider that painting in flat tints may be advantageously employed,

1. When the objects represented are at such a distance that the finish of an elaborate picture would disappear.

2. When a picture is an accessory, decorating an object whose use would forbid too elaborate finish, and which would also be too costly. Such are the paintings which ornament screens, work-boxes, tables, &c.; in this case the objects preferable as models, are those whose beauty of colours and simplicity of form are so remarkable as to attract the eye by simplicity of outline, and by vivid colours: such are birds, insects, flowers, &c.

SECTION III.

ON COLOURING IN PAINTING.

CHAPTER I.

On Colouring.

301. _True or absolute colouring_ is the faithful reproduction in painting of the modifications that light enables us to perceive in the objects taken for models.

302. In the ordinary use of the word _colouring_, we allude to the more or less perfect manner in which the painter has complied with the rules,

1. _Of aërial perspective._

2. _Of the harmony of local colours, and of the colours of the different objects composing the picture._

ARTICLE I.

Of Aërial Perspective.

303. We must not believe that the employment of many colours in a composition is indispensable to give the epithet of _colourist_ to the artist, for in pictures painted in one colour only, the simplest of all, in which we only distinguish two colours including white, the artist may be honoured with the title of _colourist_, if his work presents lights and shades distributed as they are upon the model. To convince ourselves of the justice of the expression, it will suffice to remark that the model might very well appear to the painter coloured with a single colour, modified by light and shade. In the same sense this epithet may be applied to the engraver, who, by means of his burin, reproduces a picture as faithfully as possible, in respect both to the aërial perspective of its different planes, and to the relief of each particular object.

304. A painter who has faithfully reproduced the aërial perspective, with all its modifications of white and coloured light and of shades, has effected a _true or absolute colouring_, which, however, may not be universally deemed as perfect as that in which this quality of absolute colouring is not found, at least in the same degree of perfection.

Imperfectly faithful imitation.

305. _A painter may have perfectly seized upon all the modifications of white and coloured light, but in his imitation, some of these modifications are more strongly marked than in nature._

It almost always happens that _true but exaggerated colouring_ is more agreeable than absolute colouring; and that many persons who experience pleasure in seeing the modifications of exaggerated coloured light which a picture may exhibit, do not feel the same pleasure from the sight of a model, because the modifications corresponding to those which are imitated in excess are not sufficiently prominent to be evident to them. Besides the relish of the eye for an excess of an exciting cause, is essentially analogous to the inclination we have for food and drink of a pungent flavour and odour.

306. A painter may have perfectly seized all the modifications of light which bring forward the planes and the relief of objects; the modifications of the coloured light of his picture may be true, but the colours may not be those of his model. As in pictures in which there is a dominant colour, not found in the model, which is often called _the tone of such a picture, and the tone of such a painter_, if he uses it habitually.

307. We may form a very just idea of these pictures, by supposing the artist to have painted them while looking at his model through a glass of precisely the colour, to enable him to see the tint which predominates in his imitation. We may mention as an example, of this kind of imitation, a landscape painted from its reflection in a black mirror, the effect of which is very soft and harmonious. Thus we speak of brilliant or warm, cold or dull colouring.

Of Colouring in respect to the Harmony of the Colours of the various objects composing the Picture.

308. The colouring of the picture may be _true or absolute_, and yet not agreeable in effect because the colours of the objects are not harmonious. On the contrary, a picture may please by the harmony in the local colours of each object, and by that of the colours of objects contiguous to each other, and yet may offend in its gradation of lights and shades, and by the _fidelity_ of its colours. In a word, it offends by _true or absolute_ colouring, while a picture in flat tints, the colours of which are perfectly assorted for the eye, although not those which belong to the objects imitated, produces, with regard to general harmony of colours, an extremely agreeable effect.

309. The general conclusion resulting from the analysis just made of the word colouring, is, that the epithet _colourist_ may be applied to painters endowed, in very different degrees, with the faculty of imitating coloured objects by means of painting.

310. They who know the difficulties of _chiaro-'scuro_ and drawing, may give the name of colourists to painters remarkable for the skill with which they bring out objects placed upon the different planes of their pictures, by means of correct drawing and a skilful gradation of light and shade, even when their pictures do not exactly produce every modification of coloured light, and have not this harmony of different colours properly distributed to complete the effects of perfect colouring.

311. Persons unaccustomed to judge of painting, or _chiaro-'scuro_, are generally inclined to refuse the title of colourist to such painters, while they unhesitatingly accord it to others who reproduce the modifications of coloured light, and who tastefully distribute the different colours of their pictures. Besides, the eye is so powerfully influenced by colour, that frequently those who are strangers to painting can only conceive a colourist to be skilful whose tints are vivid, although his works may evince a want of observation.

312. We see by this how judgments will differ according to the importance respectively attached to one quality of colouring rather than to another.

313. For a painter to be a perfect colourist, he must not only imitate the model by reproducing the image faithfully, with respect to the variously coloured light, but also with regard to harmony of tints in the local colours, and in the colours of the different objects imitated. And although there are colours inherent to the model, which the painter cannot change without being unfaithful to nature, yet, in every composition, there are also colours at his disposal which must be chosen so as to harmonize with the rest. We shall return to this subject in the next chapter.

314. It is thus evident, that when a change in the colours of a picture has been effected by time, it is impossible to decide whether the artist who painted it should be called a _perfect_ colourist (310). But if we refer to what I have said of the painter who has correctly seized all the modifications of light adapted to bring out the distances and relief of objects, who has truly represented the modifications of coloured light, but which are not those of the model (312), we may very easily conceive how, at the present day, after the lapse of centuries, we may apply the name of _colourist_ to Albano, Titian, Rubens, and others. In fact, the pictures of these great masters now present to us gradations, more or less perfect, of light and shade, and such harmonies of colours, that it is impossible to mistake or not to admire them; and the idea that many pictures, not more than twenty or five-and-twenty years old, painted by artists of undoubted ability, have failed in colour more than the preceding, also increases our admiration of the latter.

CHAPTER II.

Utility of the Law of Simultaneous Contrast of Colours in the Art of Colouring.

315. As to the advantages the painter will find in it when it is required,—

1. To perceive and to imitate promptly and surely the modifications of the light on the model.

2. To harmonize those colours of a composition which are essentially inherent to the nature of the objects to be produced.

316. We learn by the law of _simultaneous contrast of colours_, that when we regard attentively two coloured objects at the same time, neither of them appears of the colour peculiar to it; that is to say, such as it would appear if viewed separately, but of a tint resulting from the peculiar colour and the complementary of the colour of the other object. On the other hand, if the colours of the objects be not of the same tone, the lightest tone will be lowered, and the darkest tone will be heightened.

317. The first conclusion from this is, that the painter will rapidly appreciate in his model the colour peculiar to each part, and the modifications of tone and of colour which they receive from contiguous colours. He will also perceive and be prepared to imitate modifications in them, which, if they had not always escaped him because of their feeble intensity, might have been disregarded, because the eye is peculiarly susceptible of fatigue when it seeks to disentangle modifications, the cause of which is unknown, and which are not very prominent.

318. Let us now return to _mixed contrast_ (77 _et seq._), in order to make it evident that the painter is liable to see the colours of his model inaccurately. As the eye, after observing one colour for a certain time, has acquired a tendency to see its complementary, and as this tendency is of some duration, it follows, not only that the eyes of the painter thus affected cannot see correctly the colour which he had for some time looked at, but also whatever colour he sees while this modifying influence lasts. So that, conformably to what we know of mixed contrast, he will see,—not the colour which is before him,—but the result of this colour, and of the complementary of that seen previously. It must be remarked, that besides the want of clearness of view which will arise, in most cases, from the want of exact coincidence of the second image with the first—for example, when the eye has seen a sheet of green paper A (Plate III., fig. 4), in the first place, and, in the second place, a sheet of blue paper, B, of the same dimensions, but placed differently, this second image, not being coincident in all its surface with the first, A, as represented in the figure, the eye will see the sheet B violet only in the part where the two images coincide. Consequently, this defect of perfect coincidence of images will affect the outline of the second image, as well as the colour which it really possesses.

319. We can establish three conditions in the appearance of the same object relatively to the state of the eye; in the first, the organ simply perceives the image of the object without taking into account the distribution of colours, light, and shade; in the second, the spectator, seeking to understand this distribution, observes it attentively, when the object presents to him all the phenomena of simultaneous contrast of tone and colour that it is capable of exciting in him. In the third case, the organ, from the prolonged impression of the colours, possesses in the highest degree a tendency to see the complementary of these colours; these different states of the organ being continuous.

I have no doubt that the dull colouring with which many artists of merit have been reproached is partly due to this cause, as I shall show more minutely hereafter.

Utility of this Law to facilitate the prompt Imitation of Modifications of Light on the Model.

320. The painter, knowing that the impression of one colour beside another is the result of the mixture of the first with the complementary of the second, has only to estimate mentally the intensity of the influence of this complementary, to reproduce faithfully in his imitation the complex effect which he has before his eyes.

321. A painter wishing to imitate a white stuff with two contiguous borders, one red, the other blue, perceives each of them changed by the influence of their reciprocal contrast; thus the red becomes more and more orange, in proportion as it approaches the blue, as this latter becomes more and more green as it approaches the red. The painter, therefore, making the borders of a single red and a single blue, reduced in some parts by white or by shade, will reproduce the effects he wishes to imitate. Whenever it is found that the painting is not sufficiently marked, he is sure of what he must add without departing from the truth, farther than by exaggerating a little (305).

2. A grey pattern drawn upon a yellow ground: the ground may be of paper, silk, cotton or wool; according to its contrast, the design will appear of a lilac or a violet colour (66).

The painter who would imitate this object, can reproduce it faithfully with grey. But if a painter, ignorant of the reciprocal influence of blue and red, convinced that he must represent what he sees, adds green to his blue, and orange to his red; as in the second example, he will trace a pattern more or less violet upon the yellow ground. Now, supposing that the painter had perfectly seized the modifications of the model, and, subsequently, had retouched his copy sufficiently to produce a perfectly faithful effect, it is evident it would have been perfect only after a number of trials, since he must have effaced what was first done.

3. I cite a third example of the influence of contrast, not relating to colours, like the two preceding, but to the different tones of the same colour, contiguous to each other.

Suppose several bands in juxtaposition, 1, 2, 3, 4, (Plate 1, fig. 3), of different tones in flat tints of the same scale, to form part of an object: to imitate it perfectly, it is evident that it must be painted in flat tints; but this object will appear to the eye a channeled surface, the lines where the two bands touch will appear like a relief by the effect of contrast of tone (9-11); therefore, if the painter is ignorant of this, he will reproduce, not an absolute copy of the model, but an exaggerated one. I the more willingly cite this example, because it gave me an opportunity of enabling a most skilful paperstainer to appreciate the utility of the law of simultaneous contrast. In going with him over his factory, he showed me a chimney-board representing a child whose figure stood out from a ground formed of two circular bands in grey flat tints; 1 and 2 (Plate I., fig. 7); the first was higher than the second; the phenomenon of contrast of tone was manifested at the borders, _a a_, of the two bands, so that the part of the band 2, contiguous to the band 1, was darker than the rest, as the part of the band 1, contiguous to 2, was lighter than the rest, conformably to what has been stated above (11). This effect, not being what the skilful artist wished to obtain, he inquired of me how it was to be avoided. I replied, that the grey of the band 2 must be reduced with white, in proportion as it approached the border _a a_; and, on the contrary, the grey of the band 1 must be strengthened with black, in proper gradations, beginning at the same border. And I proved to him, _that to imitate the model faithfully, we must copy it differently from what we see it_.

322. From the above we educe the six following principles:—

1. Put a colour upon a canvas, it not only colours that part of the canvas to which the pencil has been applied, but it also colours the surrounding space with the complementary of that colour.

Thus, a red circle is surrounded with a green areola, becoming weaker as it extends from the circle:—

A green circle is surrounded with a red areola. An orange ” ” blue ” A blue ” ” orange ” A yellow ” ” violet ” A violet ” ” yellow ”

(See Plates 3, 4, 5.)

2. White placed beside a colour heightens its tone; it is as if we took away from the colour the white light which enfeebled its intensity (44-52).

3. Black placed beside a colour weakens, and in some cases impoverishes, its tone, as upon certain yellows (55). It is, in fact, adding to black the complementary of the contiguous colour.

4. Put grey beside a colour, the latter is rendered more brilliant, and at the same time it tints this grey with its complementary (63).

323. From this principle it results that in many cases where grey is near to a pure colour in the model, the painter, if he wishes to imitate this grey which appears to him tinted with the complementary of the pure colour, need not use a coloured grey, as the effect will be produced in the imitation by the juxtaposition of the colour with the grey contiguous to it.

Besides, the importance of this principle cannot be doubted, when we consider that all the modifications which a monochromous object presents (excepting those which result from the reflections of coloured lights emanating from neighbouring objects,) arise from the different relations of position between the parts of the object and the eye of the spectator; so that it is strictly true to say that, to reproduce by painting all these modifications, it suffices to have a colour exactly identical to that of the model, with black and white. In fact, with white we can reproduce all the modifications due to the weakening of the colour by light, and with black, those which are due to the height of its tone. If the colour of the model in certain parts gives rise to the manifestation of its complementary, because these parts do not return to the eye enough colour and white light to neutralize this manifestation, the modification may be imitated by the employment of a normal grey tone, properly surrounded with the colour of the object.

It is necessary, in many cases, to employ with the colour of the object the colours which are near it; that is to say, the hues of the colour. For example; in imitating a rose, we can employ red shaded with a little yellow, and a little blue, or, in other terms, shaded with orange and violet; but the green shadows which we perceive in certain parts arise from the juxtaposition of red and normal grey.

5. To put a dark colour near a different, but lighter colour, is to heighten the tone of the first, and to lower that of the second, independently of the modification resulting from the mixture of the complementaries. An important consequence of this principle is, that the first effect may neutralize the second, or even oppose it. For example; a light blue placed beside a yellow tinges it orange, and consequently heightens its tone; while there are some blues, so dark relatively to the yellow, that they weaken it so much as not only to hide the orange tint, but even to cause sensitive eyes to feel that the yellow is rather green than orange. A very natural result, if we consider that the paler the yellow, the greener it appears.

6. Put beside each other two flat tints of different tones of the same colour, chiaro-'scuro is produced, because, in setting out from the line of juxtaposition, the tint of the band of the highest tone is insensibly enfeebled, while, setting out from the same line, the tint of the band of the lowest tone becomes heightened; thus there is a true gradation of light.

The same gradation takes place in all the juxtapositions of colours distinctly separated.

I believe that attention to these principles, and especially a perfect knowledge of the consequences of the last three, exercises a very happy influence upon the art of painting, giving to the artist such a knowledge of colours as he cannot possess before the law of their simultaneous contrast and its consequences have been developed.

Among the details which the painter endeavours to render, there are many which, due to contrast, either of colour or of tone, must be produced spontaneously. I presume that the Greek painters, whose palette was composed only of black, white, red, yellow, and blue, and who executed so many pictures which their contemporaries have spoken of with intense admiration, painted conformably to the simple method of which I speak; _devoting themselves to great effects_, _many small ones resulted from them_.

Utility of the Law in order to Harmonize those Colours of a Composition which are Inherent to the Nature of the Object represented.

324. In all, or nearly all, compositions of painting, we must distinguish the colours which the painter is under the necessity of using, and those which he may choose, because, unlike the former, they are not inherent to the model (313). For example, in painting a human figure, the colour of the flesh, the eyes, and the hair, are fixed by the model; but the painter has a choice of draperies, ornaments, background, &c. In an historical picture, the flesh colours are, in the majority of the figures, at the choice of the painter,

as are also the draperies and all the accessories, which can be placed and imagined according to his judgment.

In a landscape, the colours are determined by the subject, yet not so arbitrarily but that we can substitute for the true colour that of a neighbouring scale; the artist may choose the colour of the sky, imagine numerous accidental effects, introduce into his composition animals, draped-figures, carriages, &c., of which the form and colour may be so selected as to produce the best possible effect with the actual objects of the scene.

325. A painter may also choose a dominant colour which produces, on every object in his composition, the same effect as if they were illuminated by a light of the same colour, or as if they were seen through a coloured glass (259).

326. Although the law of contrast affords different methods of imparting value to a colour, genius alone can indicate the mode in which this idea should be realized in a painting.

327. Whenever the artist would attract the eye by colours, doubtless the principle of _harmony of contrast_ must be his guide. The law of _simultaneous contrast_ indicates the means of giving value to the pure colours by each other; means which, although spoken of, are but little known, as may be commonly seen in portraits of vivid colours, badly assorted; and in those numerous small compositions in tints broken with grey, where we look in vain for a pure tone; which, however, from the objects represented in them, are eminently adapted to receive all vivid colours.

328. The contrast of the most opposite colours is as agreeable as possible, when they are of the same tone. But if crudity or too great intensity of colours is feared, we must have recourse to the light tones of their respective scales.

329. When the painter breaks tones with grey, and wishes to avoid monotony, or when on the planes which are more remote, yet not so remote as to render their differences of colour inappreciable, he wishes every part to be as distinct as possible, he must have recourse to the principle of _harmony of contrast_, and mix his colours with grey.

330. This method of bringing out a colour by contrast, in using either light tones complementary or more or less opposed, or broken tones more or less grey, and of tints complementary to each other; or, in employing a broken tone, of a tint complementary to a more or less pure contiguous colour, ought especially to fix the attention of portrait painters. A portrait will have a very poor effect when neither the colour of the dress nor of the background have been well chosen.

331. The portrait-painter must endeavour to find the predominating colour in the complexion he has to paint; and this found and faithfully reproduced, he has to seek whatever accessories at his disposal will give value to it. It is a very common error to suppose that the complexion in women, to be beautiful, must consist only of red and white: if this opinion be true for most of the women of our temperate climate, it is certain that in warmer regions there are brown, bronzed, or even copper complexions endued with a brilliancy, I may say beauty, appreciated only by those who, in pronouncing upon a new object, lay aside habitual expressions, which (albeit unconsciously to most men), exercise so powerful an influence upon their judgment of objects seen for the first time.

See the section in which I have treated of _the application of the law of contrast to dress_. (Div. V.)

332. In order to make the best use of colours without being under the necessity of multiplying them, as, for example, in draperies of a single colour, recourse may be had to the coloured rays emanating from neighbouring bodies, whether visible to the spectator or out of sight. For example, a green or yellow light falling upon part of a blue drapery renders it green, and by contrast heightens the blue-violet tone of the rest; a golden yellow light falling on part of a purple drapery imparts to it a golden tint, which makes the purple of the rest come out, &c.

333. The principle of harmony of contrast then procures for the painter in chiaro-'scuro the means of realising, with respect to brilliancy of colours and distinction of parts, such effects as are produced in paintings of flat tints.

334. Having treated of the utility of the law of simultaneous contrast in the intelligent use of pure opposite colours, and of colours broken by grey similarly opposed when it is required to multiply pure and varied colours, it now remains for me to treat of those cases in which the painter, desiring less diversity in the object, less variety in the colours, employs sparingly the _harmony of contrast_, preferring the _harmony of scale_ and the _harmony of hues_.

335. The greater the variety of colours and accessories in a composition, the more the eyes of the spectator are distracted, and the more difficulty is experienced in fixing attention. If then, this condition of diversity of colours and accessories is obligatory on the artist, the more obstacles there are to surmount in drawing and fixing the attention of the spectator upon the physiognomy of the

figures, whether they represent the actors in a single scene, or whether they are simply portraits. In the latter case, if the model has such an ordinary physiognomy, as recommends itself neither by its expression nor its beauty, and still more, if he must conceal or dissemble a natural defect, all that is accessory to this physiognomy, all the resources of contrasted colours, well assorted, should come to his aid.

336. But if, fervently inspired, he appreciates the purity of expression, the nobility and loftiness of character pertaining to his model; or even if a physiognomy, to most eyes commonplace, strikes him by such an expression as he judges to belong only to men animated by noble ideas, it is to such a model that he will address himself and fix his chief attention; so that in giving it life upon his canvas, no one can mistake either the resemblance, or the sentiment which directed his pencil. Everything being accessory to the physiognomy, the draperies will be of black or of sombre colours; and if ornaments relieve them, they will be simple, and always in keeping with the subject.

337. When, in this point of view, we examine the masterpieces of Vandyke, and trace the beauty of their effect to the simplicity of the means which produce it,—when we consider the elegance of their attitudes, which always appear natural, the taste which presided over the selection of all the accessories, we are struck with admiration of the genius of the artist, who has not had recourse to those means, so much abused at the present day, of attracting attention, either by giving to the most vulgar person an heroic attitude, to the most commonplace physiognomy pretension to profound thought, or by seeking extraordinary effects of light, such as filling the figure with a strong light, while the rest of the composition is in shade.

338. These reflections indicate the course which an historical painter must take, when he would particularly fix the attention upon the physiognomy of the persons in a remarkable scene. The more he employs allied scales, the more care he must take to select such as do not lose too much by their mutual juxtaposition.

339. There is another important direction to give, which is to avoid as much as possible the same kind of images on different objects; thus figures clothed in draperies with large flower patterns, in a room where the carpet and porcelain vases repeat the same images, are never free from objection, for it is troublesome to the eye to distinguish those parts of the picture which the similarity of ornaments tends to confound. Upon the same principle, the painter must generally avoid placing beside the faithful copy of a model the copy of an imitation which repeats this model. For example, when, he paints a vase of flowers, the artist produces most effect, other things being equal, in painting a vase of grey or white porcelain, instead of a vase upon which a profusion of similar objects are its ornaments.

340. When it is required that a certain colour shall predominate in a composition, or to speak more correctly, when the scene is illuminated by a coloured light, shed over every object, we must not only take simultaneous contrast into consideration, but also the modification which results from the mixture of colours (172), comprising the recomposition of white light by means of a proper proportion of the differently coloured elementary rays.

341. We must here attentively study the article which treats of the principal cases of the modifications of light resulting from coloured rays falling upon bodies of various colours (261, _et seq._), when, although the coloured light chosen imparts value to certain colours of the objects upon which it falls, it also impoverishes and even neutralizes others. Consequently, in employing any predominant colour, we must renounce the advantages of others, or the effect produced will be false. For example: if orange colour predominates, for the colouring to be true it must necessarily follow—

1. That the purples must be more or less red. 2. That the reds must be more or less scarlet. 3. That the scarlets must be more or less yellow. 4. That the orange must be more intense, more vivid. 5. That the yellows must be more or less intense, and orange. 6. That the greens lose their blue, and consequently become yellower. 7. That the light blues become more or less light grey. 8. That the deep indigo becomes more or less maroon. 9. That the violets lose some of their blue.

Thus we see that orange light heightens all the colours which contain red and yellow, while, neutralizing a portion of blue in proportion to its intensity, it destroys wholly or partially this colour in the body which it illuminates, and consequently disturbs the greens and the violets.

342. With reference to the true imitation of colouring, it appears to me that painters of interiors, have, other things being equal, more skill than historical painters in faithfully reproducing the modifications of light. Historical painters, attaching more importance to the attitudes and physiognomy of their figures than to the other parts of their composition, attend less to small details, the faithful imitation of which is the essential merit of the painter of interiors. Besides, the historical painter is never in a position to see the

whole of the scene he would represent, while the painter of interiors, having constantly his model before him, sees it completely, as he imitates it upon the canvas. Hence, therefore, in every small composition the colours, as well as the objects represented, must be distributed with a kind of symmetry, so as to avoid being what I can best express by the term _spotty_. In fact, for want of a good distribution of objects, the canvas will not be filled in some parts, or, if it is, there will be, in many places, evident confusion; so also if the colours be not properly distributed, the picture will be spotty, because they are too far isolated from the others. (See 249-251.)

343. I believe that those painters who will study the mixed and simultaneous contrasts of colours, in order to employ rationally the coloured elements of their palette, will perfect themselves in _absolute colouring_ as by studying the principles of geometry they perfect themselves in linear perspective. I have no doubt but that the difficulty encountered by painters ignorant of the law of contrast, of faithfully imitating their model, has been with many the cause of a colouring dull and inferior to that of artists, who, less careful than they in the fidelity of imitation, or not so well organized for seizing all the modifications of light, have worked more by their first impressions, or, in other words, seeing the model more rapidly, their eyes have not had time to become fatigued; and thus, content with the imitation which they have made, they have not returned to their work too often to modify, to efface, and afterwards to reproduce it upon a canvas soiled by the colours first put on. There are, indeed, many painters, to whom the maxim, “Let well alone,” is peculiarly applicable.

SECOND DIVISION.

Imitation of Coloured Objects by Materials of a Definite Size, as Threads, &c.

344. The tapestries of Gobelins and of Beauvais, and also the carpets of Savonnerie, and certain very elaborate mosaics, may all be considered as works which resemble the method of painting in _chiaro-’scuro_; while the windows of Gothic churches correspond more or less exactly to painting in _flat tints_; so also with tapestries for furniture and carpets, which, instead of being fabricated with scales of at least sixteen or eighteen tones, as they are in the royal manufactories, are composed with scales consisting of three or four tones only, and, far from imitating the effects of _chiaro-’scuro_, the coloured objects produced present to the eye only small monochromous bands of a single tone.

345. There are also some works whose coloured designs are upon a kind of mixed system, being the result of the juxtaposition of monochromous single tinted parts, of a visible size, but in which the effects of _chiaro-’scuro_ are sought by using gradations of scale or a mixture of hues; such are ordinary mosaics, carpets, embroidered tapestries, &c.

346. In the patterns of tapestries and carpets, when the principal effects to be aimed at have been determined, it may be seen what points of ordinary painting may be sacrificed to obtain them, and what must be done for perfecting the _special portion of their imitation_. Beginning with the physical condition of the coloured elements the weaver employs, and the texture of the tapestry, we see the necessity of representing in this kind of work only large, well-defined objects, and especially such as are remarkable for the brilliancy of their colours. The patterns for hangings must recommend themselves more by the opposition of their colours than by the minute finish of their details. To pretend to rival painting in these manufactures is to establish a confusion most detrimental to the progress of arts, absolutely distinct from painting, both in their purpose and their means of execution.

347. The principles truly essential to these arts of imitation being once deduced from the peculiarities of each, it becomes easy to point out by what efforts we may hope to obtain true perfection.

CHAPTER I.

ON THE ELEMENTS OF GOBELINS TAPESTRY.

348. To make mixtures of coloured threads intelligently, we must be guided by the three following rules:—The first two resulting directly from observation of facts; the third being the natural deduction from the facts comprised in the two former.

RULE I.—THE BINARY MIXTURE OF PRIMARY COLOURS.

When we unite Red with Yellow, Red with Blue, Yellow with Blue, the threads must not reflect a perceptible quantity of the third primary colour, if we would have Orange, Violet, and Green as brilliant as it is possible, by this method, to obtain.

EXAMPLE A.—_Red and Yellow._

Plate 11.

3 Red threads with 1 Yellow thread, 2 ” ” 1 ” ” 1 ” ” 1 ” ” 3 Yellow ” 1 Red ” 2 ” ” 1 ” ”

yield mixtures which appear to the eye in proportion to the two colours mixed. There is no appearance of grey in any of these mixtures, when we employ a red more inclining to orange than to crimson, and a yellow more inclining to orange than to green.

[Illustration: PLATE XI.]

B.—_Red and Blue._

3 Red threads with 1 Blue thread, 2 ” ” 1 ” ” 1 ” ” 1 ” ” 3 Blue ” 1 Red ” 2 ” ” 1 ” ”

yield mixtures which appear to the eye in proportion to the two colours mixed. If we use a red and a blue inclining to violet, the mixture will contain no grey.

C.—_Yellow and Blue._

4 Blue threads with 1 Yellow thread, 3 ” ” 1 ” ” 2 ” ” 1 ” ” 1 ” ” 1 ” ”

give mixtures which appear to the eye in the proportions of the two colours mixed. If we use yellow and a blue inclining to green more than to red, the mixture will contain little or no grey.

Experiment on all the preceding mixtures demonstrates the rule above; or rather, this rule is but the expression of a generalization of facts.

RULE II.—THE MIXTURE OF COMPLEMENTARY COLOURS.

349. _When we mix Red with Green, Orange with Blue, Yellow with Violet, the colours are more or less completely neutralized, according as they are more or less perfectly complementary to each other, and as they are mixed in proper proportions. The result is a grey, the tone of which is generally higher than that of the colours mixed, if the latter are of a suitably high tone._

EXAMPLES.—_Red and Green._

Plate 12.

3 Red threads with 1 Green thread give a dull Red.

2 Red threads with 1 Green thread give a duller and a deeper Red.

1 Red thread with 1 Green thread give a Reddish-grey.

The tone a little higher than the preceding.

3 Green threads with 1 Red thread give a Green Grey, the tone higher than the Green or the Red.

2 Green threads with 1 Red thread give a Grey, less Green, and of a higher tone than the two colours.

In repeating the same mixtures with higher tones of the same scales of Green and Red, the tone of the mixture of 2 Green with 1 Red is higher relatively to that of the colours mixed, than it is in the mixtures above.

1 Red thread and 1 Yellowish-green thread give a Carmelite-brown or an Orange-grey, the tone of which is equal to that of the colours mixed.

1 Red thread and 1 Bluish-green thread give a copper-coloured mixture or catechu-brown of a higher tone than that of the colours mixed.

Hence we may conclude that red and green threads, properly assorted, and in suitable proportions, yield _Grey_.

Orange and Blue.

3 Orange threads with 1 Blue thread give a dull Orange. 2 Orange ” 1 ” ” a duller Orange. 1 Orange ” 1 ” ” Chocolate-grey. 3 Blue ” 1 Orange ” Violet-grey. 2 Blue ” 1 Orange ” Violet-grey. Redder than the preceding.

[Illustration: PLATE XII.]

The results are the same with deeper tones than the preceding, except that the corresponding mixtures are browner.

3 orange threads with 3 blue threads present a remarkable phenomenon, according to the intensity of the light and the position from which it is observed. The tapestry being placed in a vertical plane before the incident light when the warp is horizontal, we perceive _blue_ and _orange_ stripes; but if the warp is vertical, we may then see the upper part of each blue stripe _violet_, and its under part, as well as the upper part of each orange stripe _green_, while the rest of each of the latter will appear _red_, bordered on the lower part with _yellow_. We may also see the upper part of each blue stripe, _violet_, and its under part, as well as the upper part of each orange stripe, _green_, and the rest of each of these stripes _red_, bordered on the lower part with green, and in the upper part with yellow. We say that they may be seen in this manner, because if the light were strong enough for distinct vision, we should not see the horizontal blue and orange stripes.

Yellow and Violet.

3 Yellow threads with 1 Violet give a Greyish-yellow. 2 ” ” 1 Violet ” Yellow-grey. 1 ” ” 1 Violet ” Grey, much nearer _normal grey_ than the preceding.

3 Violet threads and 1 Yellow give a Greyish-violet. 2 ” ” 1 Yellow ” dull Violet, greyer than the preceding.

It is remarkable that in the mixture of a yellow with a violet thread, seen from a greater distance than that at which they appear neutralized, the yellow is so much weakened in proportion to the violet, that the mixture appears of a dull violet.

Yellow and blue afford an analogous result.

RULE III.—THE MIXTURE OF THE THREE PRIMARY COLOURS IN SUCH PROPORTIONS THAT THEY DO NOT BECOME NEUTRALIZED, BECAUSE ONE OR THE OTHER OF THEM IS IN EXCESS.

350. _When Blue, Red, and Yellow are combined in such proportions that they do not neutralize each other, the result is a colour much greyer or more broken than if the proportion of complementary colour were more equal._

As Red mixed with a Greenish-yellow gives a _Carmelite_ mixture, I shall add the following:—

1. _Crimson-red and greenish-yellow_ give mixtures so much duller as these colours more nearly neutralize each other. A mixture of one crimson-red with one greenish-yellow thread produces a brick or copper-orange, the tone of which is higher than that of the colours mixed.

2. _Scarlet-red and greenish-blue_ give mixtures which are without vigour or purity, relatively to the corresponding mixtures made with crimson-red and violet-blue.

3. Red and blue-grey give violet mixtures, which are not so dull as the preceding, because the colours contain no yellow.

4. The red of the mixture 3, worked with a green-grey, gives mixtures much duller than the preceding, as might have been expected, on account of the yellow contained in the green-grey.

5. Orange and blue-violet give very dull mixtures.

6. Orange and red-violet give dull mixtures, but redder or less blue than the preceding.

ON THE PRINCIPLE OF CONTRAST IN CONNEXION WITH THE PRODUCTION OF TAPESTRY.

351. The tapestry-weaver should therefore thoroughly understand the effects of contrast, to know the influence which the part of the copy he proposes to imitate receives from the colours surrounding it, and so judge what coloured threads to choose. The following examples will explain better than the most profound reasoning the necessity for the tapestry-worker to possess a knowledge of the law of contrast.

First Example.

352. If there be two coloured stripes in a picture, one red the other blue, touching each other, the phenomenon of contrast between two contiguous colours would have arisen, had not the painter sustained the red by blue, and the blue stripe by making it red or

violet next to the red stripe (320).

353. Suppose a weaver wishing to imitate these two stripes, but ignorant of the law of contrast of colours, after choosing the wools or silks, he is sure to make two stripes, which will produce the phenomenon of contrast; for he will select his wools or silks of only one blue or one red, to imitate two stripes of different colours, each of which appears homogeneous throughout, but which the painter has only succeeded in making so by neutralizing the phenomenon of contrast, which would undoubtedly have resulted had each been painted of a uniform colour.

354. Suppose the painter has painted the stripes with uniform colours, then contrast will arise, so that the red contiguous to the blue will appear orange, and the blue contiguous to the red will appear greenish.

If the weaver be ignorant of the law of contrast, in attempting to imitate his model he will be sure to mix yellow or orange with his red, and yellow or green with his blue, in those parts of the stripes which come in contact. Hence the contrast will be more exaggerated than if he had worked the two stripes with homogeneous colours.

355. Suppose a weaver has to copy the series of ten grey stripes in flat tints (fig. 3, Plate 1) described (11), it is evident that if he is ignorant of such effects he will exaggerate it in the imitation; for instead of working ten tints of the same scale so as to produce ten bands in flat tints, he will make ten bands, each graduated conformably to what he sees; he will probably also have recourse to lighter and darker tones than those which correspond exactly to the model, and thus he will require a greater number of tones than would have been necessary had he been aware of contrast, rendering the copy an exaggeration of the model.

When we attentively observe the rosy flesh tints of many pictures, we perceive in the shadows a more or less apparent green tint, resulting from the contrast of rose with grey. (I presume that the painter has made his shadows without using green, and that he has not corrected the effect of contrast by using red.) Now a weaver, ignorant of the effect of rose upon grey, in imitating the shaded part will have recourse to a green-grey, which will exaggerate an effect that would have been produced naturally by employing a scale of pure, not of greenish grey.

QUALITIES WHICH PATTERNS FOR GOBELINS TAPESTRY MUST POSSESS.

356. To determine the qualities which model pictures for tapestry must possess, we must decide what are specific qualities peculiar to this kind of imitation.

The weaver imitates objects with coloured threads of a certain diameter. These threads are applied round the threads of the warp. Their surface is not uniform but furrowed, those which are parallel to the threads of the warp being lower than those which are perpendicular to it; the effect of these furrows being such as would be produced upon a picture, by a series of dark parallel lines, cut at right angles by another series of finer parallel lines, less dark than the preceding.

357. There are these differences then between tapestry and painting:—

1. Tapestry never presents those blended colours which the painter obtains so easily by indefinitely mixing or dividing his pigments.

2. The symmetry and uniformity of the furrows of tapestry prevent the lights being as vivid, and the shadows as vigorous, as in a painting; for though the furrows obscure the lights, the salient parts of the threads which are in the shades, have the ill effect of enfeebling the latter by the light they reflect.

3. The lines surrounding the different objects in a painting, although straight or curved in every direction, may be of extreme fineness without ceasing to be perfectly distinct, while the threads of the weft and the warp, always crossing at right angles, interfere with such a result whenever the lines of the pattern do not exactly coincide with these threads.

4. The painter has other resources, which are denied to the weaver, for increasing the brilliancy of the lights and the vigour of the shadows. For instance: he opposes opaque body-colours to glaring colours, he modifies an object of a single colour by varying the thickness of the layer of paint which he places on the canvas; and within certain limits he can produce modifications, by changing the direction of the strokes of his pencil.

358. Hence, to raise the effects of tapestry as nearly as possible to those of painting, it is requisite:—

1. That the objects be represented of such a size that the position of the spectator does not permit of his distinguishing either the coloured elements from each other, or the furrows which separate them; so that threads of two mixed scales (377), and the

hatchings of different scales, more or less distant, interwoven together (378), may be mingled into a homogeneous colour, and that the cavities and salient parts may appear as a uniform surface.

2. That the colours be as vivid and strongly contrasted as possible, so that the lines which surround the different objects be more distinct, and the lights and shadows be as different as possible.

359. Thus patterns for tapestry must not only recommend themselves by correct outline and elegant forms, but must also represent larger objects: figures draped rather than nude, vestments decorated with ornaments, rather than simple and uniform. Consequently, every thing allied to miniature, by minuteness or by finish in details, is foreign to its special object.

360. The elements of Beauvais tapestry for furniture are essentially the same as those of Gobelins tapestry; but with this difference, that the light and the middle tones are of silk, while in the Gobelins tapestry these tones are almost always of wool. The scales of Beauvais are less varied in colour than those of the Gobelins, and their tones are less numerous. But the working of the threads is the same in both kinds of tapestry; so that as to the employment of coloured threads, depending in like manner on the knowledge and observance of the principles of mixture and contrast of colours, I need not add to what I have already said on this subject in the preceding section.

361. The furrows caused by the weft and the warp have not the inconvenience they present in the Gobelins tapestry. In fact, the regular grain of the tapestry for furniture is so far from producing a bad effect in the image represented on it, that we are obliged to give the appearance of this grain to many paper-hangings by means of parallel lines cutting it, or by points symmetrically placed.

COLOURED GLASS WINDOWS IN LARGE GOTHIC CHURCHES.

362. I am about to examine, according to the preceding views, the coloured glass windows which concur so powerfully with architecture, in giving to vast gothic churches that harmony which we cannot fail to recognise whenever we enter them. These structures rank with those works of art which are most impressive by their size, the subordination of their various parts, and by their complete fitness for the purposes to which they are applied. The stained glass of gothic churches has always a most appropriate effect, intercepting the white light, which, by giving too vivid a glare, is less conducive to meditation than the coloured light which this glass transmits. We shall find its splendid effect to arise, not only from the contrast of colours, but also from the contrast of its transparency with the opacity of the surrounding walls, and of the lead which binds its parts together. The impression produced on the eye by this twofold cause becomes more vivid the more frequently it is repeated and the longer it is sustained, when yellow, blue, violet, orange, red, and green stained glass appears like most precious jewels.

363. The upright windows usually represent, within a border or a ground analogous to the rose windows, the figure of a saint in harmony with those which stand in relief about the portals of the edifice; and to be fully appreciated they must be judged of as _parts of a whole_, and not as a Greek statue which is intended to be seen isolated on all sides.

The glass is of two kinds, the one painted on its surface by pigments afterwards vitrified (glass painting); the other, melted with the material that colours it (glass staining); the first is generally used in the composition of the nude parts of the human figure, and the second in that of the drapery. All the pieces of glass are united by strips of lead. What has struck me as being most effective in windows with human figures, is the exact observance of the relations of size of the figures and of the intensity of the light which renders them visible, with the distance at which the spectator is placed; a distance at which the strips of lead surrounding each piece of glass appear only as lines or as small black bands.

364. It is not necessary, for an effective whole, that the _painted glass_, when viewed closely, should exhibit fine hatchings, careful stippling, or blended tints; for, with the coloured stained glass for draperies, they should compose a system which compares with painting in flat tints, and certainly we cannot doubt that a painting on glass, executed entirely according to the system of _chiaro-scuro_, not to speak of the cost of its execution, will have the disadvantage of the finish in its details entirely disappearing at the distance at which it must be viewed as a whole.

365. _The first condition, which must be fulfilled by every work of art, is, that it be presented without confusion and as distinctly as possible._ Let us add that paintings on glass, executed on the method of _chiaro-'scuro_, cannot receive the borders and grounds of rose windows which have such fine effects of colour, as they have less brilliancy and transparency than the glass in which the colouring material has been incorporated; they are also less capable of resisting the injuries of time.

Variety of colours in these windows is so necessary to attain the best possible effect, that those which represent figures entirely nude, edifices, or large objects of a single colour, or slightly tinted, whatever may be the perfection of their execution with regard to finish or truth of imitation, will have an inferior effect to windows composed of pieces of varied colours suitably contrasted; but a bad effect results from the mixture of coloured glass with transparent colourless glass, when the latter has a certain extent of surface in a window; yet a good effect is obtainable by mixing ground glass with coloured glass, and also of small pieces of colourless transparent glass, framed in lead, so that at the distance at which they must be viewed they produce the effect of a symmetrical juxtaposition of white parts with black parts.

366. I conclude that we must refer the causes of the beautiful effects of coloured glass of great churches—

1. To their presenting a very simple design, whose different well-defined parts may be seen without confusion at a great distance.

2. To their offering a union of coloured parts which are distributed with a kind of symmetry, but which are also vividly contrasted, not only among themselves, but also with the opaque parts which surround them.

367. Coloured windows appear to me to produce their utmost effect only in the vast edifices where the different-coloured rays reach the eye of the spectator on the floor of the church so much scattered that they impinge upon each other, whence results an harmonious mixture, not found in a small structure lighted by coloured windows. It is this intimate mixture of the coloured rays, transmitted into a vast edifice, which permits of tapestries placed on the ground floor. But when the lower walls have not colourless glass windows, it is evident that, if tapestries be placed too near coloured windows, the harmony of their colours must be lost, as when blue rays fall upon red draperies, yellow rays upon blue draperies, &c.

Thus, when coloured glass is to be put in a window, it is necessary to take into consideration, not only its beauty, but also the effect which the coloured light it transmits will have upon the objects illuminated by it.

368. The coloured windows of a large church may be regarded as real, transparent tapestries, intended to transmit light, and to ally themselves harmoniously with the sculptures on the exterior, which destroy the monotony of the high walls of the edifice, and with the different monuments of the interior, among which tapestries must be taken into account.

369. My ideas on the employment of stained glass for windows may be summed up in the following terms:—

1. They produce their utmost effect only in the rose windows, bay windows, or pointed windows of large Gothic churches.

2. Only when they present the strongest harmonies of contrast, not of colourless transparent glass with the black produced by the opacity of the walls, iron bars, and strips of lead, but of this black with the intense tones of red, blue, orange, violet, and yellow.

3. Their designs must always be as simple as possible, and admit of the harmonies of contrast.

4. While admiring painted windows, of which a large number consist of paintings of undoubted merit, especially in regard to the difficulties overcome, I confess that it is a kind of painting which should not be much encouraged, because it never has the merit of a picture properly so called, it is more costly, and will produce less effect in a large church than a stained window of much lower price.

5. Windows of a pale grey ground, with light arabesques, have a very poor effect wherever they are placed.

See the relations of the law of contrast with the decoration of the interiors of churches.

THIRD DIVISION.

Colour Printing.

ON CALICO-PRINTING, AND PRINTING PAPER-HANGINGS.

370. I propose to examine only the optical, not the chemical, effects produced by patterns printed upon woven fabrics.

Printing on textile fabrics was for a long time limited, so to speak, to cotton cloths. It is only of late years that it has been extended to fabrics of silk and wool, for furniture and clothing. This branch of industry has now undergone an immense extension, fashion having accepted these products with extreme favour; but, whatever may be the importance of the subject, in a commercial point of view, I must treat it briefly. This book is not directed exclusively to that branch of inquiry, and as all the preceding part is intimately

connected with it, I shall merely state some facts which show, that, in ignorance of the law of contrast, the manufacturers and printers of cotton, woollen, and silk stuffs are constantly exposed to error in judging the value of recipes or colours, or as to the true tint of the design applied upon grounds of a different colour.

FALSE JUDGMENT OF THE VALUE OF RECIPES FOR COLOURING COMPOSITIONS.

371. At a certain calico-printer's a recipe for printing green had always succeeded up to a certain period, when it began to give bad results. They were lost in conjectures upon the cause, when a person, who at the Gobelins had followed my researches on contrast, recognised that the green of which they complained, being printed on a ground of blue, inclined to yellow through the influence of orange, the complementary of the ground. She therefore advised that the proportion of blue in the colouring composition should be increased in order to correct the effect of contrast. The recipe, modified according to this suggestion, gave the beautiful green which they had obtained formerly.

372. Thus every recipe for colours to be applied upon a ground of another colour, must be modified conformably to the effect which the ground will produce. It is this great facility in correcting the ill effect of certain contrasts which explains why they so often succeed without being able to account for it. Here, notwithstanding their colour, the eye judges them to be colourless, or of the tint complementary to that of the ground. These appearances have been the subject of questions frequently addressed to me by the manufacturers of printed stuffs, and by drapers: they are due to the _law of simultaneous contrast of colours_. In fact, when the patterns appear white, the ground acts by contrast of tone (9); if they appear coloured (and this appearance generally succeeds to that where they appear white), the ground then acts by contrast of colour (13). The manufacturer of printed stuffs therefore will not seek to attribute the cause of these phenomena to the chemical actions in his operations.

373. Ignorance of the law of contrast has, among drapers and manufacturers, been the subject of many disputes, which I have been happy to settle amicably, by demonstrating to the parties that they had no possible cause for litigation in the cases they submitted to me. I will relate some of these, to prevent similar disputes.

Certain drapers gave to a calico-printer some cloths of single colours, red, violet, and blue, upon which they wished black figures to be printed. They complained that upon the _red_ cloths he had put _green_ patterns; upon the _violet_, the figures appeared _greenish-yellow_; upon the _blue_, they were _orange-brown_ or _copper_-coloured—instead of the _black_ which had been ordered. To convince them that they had no ground for complaint, it sufficed to have recourse to the following proofs:—

1. I surrounded the patterns with white paper, so as to conceal the ground; the designs then appeared black.

2. I placed some cuttings of black cloth upon stuffs coloured red, violet, and blue; the cuttings appeared like the printed designs, _i. e._, of the colour complementary to the ground, although the same cuttings, when placed upon a white ground, were of a beautiful black.

374. The modifications which black designs undergo upon different coloured grounds are the following:—

Plate 13.

Upon _Red_ stuffs they appear Dark Green.

Upon _Orange_ stuffs they appear of a _Bluish-black_.

Upon _Yellow_ stuffs they appear _Black_, the violet tint of which is very feeble, on account of the great contrast of tone.

Upon _Green_ stuffs they appear of a _Reddish-grey_.

Upon _Blue_ stuffs they appear of an _Orange-grey_.

Upon _Violet_ stuffs they appear of a _Greenish-yellow Grey_.

[Illustration: PLATE XIII.]

These examples are sufficient to enable us to comprehend their advantage to the printer of patterns in colours complementary to the colours of the ground, whenever contiguous tints are to be mutually strengthened without going out of their respective scales.

DESIGNS FOR PAPER-HANGINGS.

375. The manufacture of paper-hangings has now arrived at such a point, that a knowledge of the law of contrast of colours is indispensably necessary to this branch of industry. We cannot estimate the true relations between the law of contrast and the art of paper-staining without dividing the papers into several categories to which the law is applicable.

1. Papers having figures and landscapes, or flowers of different sizes, and of varied colours, not intended for borders; these approach the nearest to painting.

2. Papers with patterns of one colour, or of colours but slightly varied.

3. Those employed as borders.

CHAPTER II.

On the Law of Simultaneous Contrast of Colours in relation to Paper-Hangings with Figures, Landscapes, or large Flowers of varied Colours.

376. The study which I recommend to artists occupied in fabricating paper-hangings, is in some measure that immediately applicable to every pictorial composition, or, in other words, the tapestry of figures and landscapes. But, whatever be the merit of paper-hangings of this category, they are not sought by persons of refined taste, and they do not appear to me destined to be any more so in future, for the twofold reason that the taste for arabesques, painted upon walls, or upon wood, and that for lithographs, engravings, and paintings, is spreading every day. These last three objects exclude, at least, all those papers with figures and coloured landscapes.

377. The applications of the law of contrast to this class of paper-hangings are easy, when we thoroughly understand the divisions of the book to which I referred above. In order to prove the advantage to be derived from the knowledge of this law, I need only refer to the bad effect presented by contiguous bands of two tones of the same scale of grey (serving as the ground to the figure of an infant), in consequence of the contrast of tone arising from their juxtaposition (321).

378. _On the Law of Simultaneous Contrast of Colours in relation to Paper-hangings with Designs in a Single Colour, or in Colours but slightly varied._

The remarks in 372 are applicable here also, as are those of 374. The best executed, and in the best taste, are those with black figures, or of figures much darker than the ground.

Paper-hangings, I do not say the most tasteful, but those most convenient for use, present very light grounds, with white or grey figures.

379. Grey patterns, upon papers tinted of a light colour, exhibit the phenomenon of maximum contrast; that is to say, the grey appears coloured with the complementary of the ground.

[Illustration: PLATE XIV.]

Thus, conformably to the law, (Plate 14)

Grey patterns upon a _Rose_ ground appear _Green_. ” ” ” an _Orange_ ” ” _Blue_. ” ” ” a _Yellow_ ” ” _Violet or Lilac_. ” ” ” a _Green_ ” ” _Rose_. ” ” ” a _Blue_ ” ” _Orange-grey_. ” ” ” a _Violet_ ” ” _Yellow_.

380. I mention these examples to instruct artists, for, in manufactories of paper-hangings, disputes arise between the proprietors and the preparers of the colours. For instance, a few years ago, the proprietors of one of the first manufactories in Paris, wishing to print grey patterns upon grounds of apple green and of rose, refused to believe that his colour preparer had given any _grey_ to the printer, because the designs printed on these grounds appeared coloured with the complementaries of the colour of the ground. It was only when the colour preparer, having attended a lecture I gave for M. Vauquelin, at the Museum of Natural History, and hearing me speak of the mistakes that these contrasts of colours might occasion, suspected the cause of the effects which he had unconsciously produced, and which had really caused him much annoyance.

OF THE LAW OF SIMULTANEOUS CONTRAST OF COLOURS RELATIVELY TO THE BORDERS OF PAPER-HANGINGS.

381. Every paper of one colour, or one belonging to the second category, should receive a border generally darker and more complex in design and colour than the paper which it frames.

The assortment of two papers exercises a very great influence on the effects they are capable of producing; for each of them may be of a fine colour, ornamented with designs in the best taste, yet their effect will be mediocre, or even bad, because the assortment will not be conformable to the law of contrast.

382. The ground of a border contributes greatly to the beauty of the pattern, whether this be of flowers, ornaments, or any other object. As we cannot treat of this influence in an absolute or methodical manner, I shall select a certain number of remarkable facts which I have had occasion to observe, and I shall principally dwell on those from which we can deduce conclusions, which, apparently not flowing from previous observation, might escape many readers, in spite of the great interest they have in knowing them. Besides, the exhibition of these facts will give me occasion to apply the law of contrast to designs presenting many tones of the same scale, and of different hues, and also often of different scales, more or less distant from each other. I shall not treat of simple borders, presenting black or grey designs upon a uniform ground, for I have already spoken of the modifications which in this case black designs undergo (374), and grey designs also (379).

383. The design of a border, either of ornaments, flowers, or any other object, being cut out and pasted upon a white card, designs identical with the preceding, which had been pasted upon cardboard, were then cut out, and placed upon grounds of black, red, orange, yellow, green, blue, and violet; then compared, not only by myself, but also by many persons whose eyes are much accustomed to seeing colours. When we had perfectly agreed upon their value, the results were noted as follows:—

1.—BORDER OF EIGHT INCHES IN HEIGHT, REPRESENTING GILT ORNAMENTS UPON DIFFERENT GROUNDS.

Plate 15.

[Illustration: PLATE XV.]

384. These ornaments, executed by the ordinary processes of paper-staining, contained no particle of metallic gold; yellow, lakes, and orange, of different tones and hues, had been exclusively employed in their production. After having stated the modifications which the painted gilt ornaments experience from the colour of the grounds, I shall indicate those which the metallic gilt ornaments receive comparatively from the same grounds; this comparison presenting results which appear to me interesting.

Black Ground.

385. Painted gilt ornaments placed upon black ground, compared with the same ornaments placed on a white ground, appear much more distinct than the latter; because the yellows and orange-yellows, colours eminently luminous, and the black ground, which reflects no light, give rise to contrast of tone, which the white ground, essentially luminous, cannot give with the colours which are themselves luminous. (See 53.)

We perceive thus, that the colours placed upon black are lowered in tone; but it must be noted that yellows and orange-yellows, far from being weakened (58), would only cause the black to gain in purity.

In considering more particularly the effects of two grounds, we see that a black imparts a red to the ornaments, and it is important to remark that the brightness of this red, instead of reddening the yellows, really gilds them. (See 394.)

We may thus understand how black, in taking away some grey, imparts brilliancy, and how this grey, which may be considered as a tarnished or subdued blue, may, with yellow, produce an olive colour. It is also necessary to remark, that the gilt ornaments in question present an olive-grey tint, which, far from being diminished by the white ground, is exalted by it.

Although the black ground lowers the tone of the colours, while white heightens them, it lowers yellow more in proportion than red, and consequently renders the ornaments redder than they appear upon a white ground; and, in taking away the grey, it purifies the colours, and acts also by giving them some red, or by taking away some green.

Metallic Gilt Ornaments.

386. Gilt ornaments stand out better from black than from white, but the orange colour is weakened and really impoverished. The black ground then does not purify the real gilt ornaments as it does the painted imitation of gold.

Deep Red Ground.

The yellows are more luminous, the whole effect with the painted ornament is clearer, more brilliant, less grey than upon a white ground.

Red much deeper than the ornament, lowers the tone of it; and this effect is also augmented by the addition of its complementary, green, a bright colour.

This example is of much importance, enabling us to see how the red, which appears as though it could be of but little advantage to ornaments, because it tends to weaken them by making them greener, is notwithstanding favourable, because the lightening or weakening of the colour is more than compensated for by the brilliancy of the complementary of the ground which is added to the yellow. We shall return to this effect in a moment. There is this analogy between the influence of the red ground and that of the black ground, that the tone of the colour is lowered; but there is this difference, that the ornaments become green on the first, while they become orange upon the second.

387. The red ground is not so advantageous for gilt ornaments as it is for the painted imitations of them, because the metal loses too much of its orange colour, and appears inferior to gold upon a black ground.

The red ground appears darker, and more violet than the ground upon which painted ornaments are placed.

Grounds of a light-red are still less favourable to the gold than red grounds of a dark tone.

Orange Ground deeper than the Ornaments.

388. The painted ornaments are bluer or rather greener than upon a white ground. The yellow and orange are singularly lower in tone.

This ground, then, is very disadvantageous to ornaments, as might have been expected.

389. Orange is not favourable to metallic gilt. The metal becomes too white, while the orange ground is redder and more vivid than that upon which the painted ornaments are placed.

Yellow Ground of Chromate of Lead more brilliant than the Yellow of the Ornaments.

390. The yellow of the painted ornaments is excessively enfeebled by the complementary of the ground which is added to it, the ornaments appear grey in comparison with those upon a white ground.

391. The yellow ground is not so unfavourable to gilt ornaments as it is to painted ones. The first assortment may, in certain cases, be recommended.

The yellow appears more intense, and perhaps greener.

Bright Green Ground.

392. Painted ornaments are darker upon a bright green ground than upon a red or white ground. They have acquired some red, but not the brilliant tint which is given to them by black—it is a brick-red tint.

393. It follows from the comparison of the effects of ornaments upon red and upon green grounds, that the first is much more advantageous than the second, because it adds an essentially brilliant tint to the colour of the ornaments, while the latter, adding red, or taking away green, produces a brick-red.

394. Upon a bright green ground, _metallic gilt ornaments_ acquire red, as the painted ornaments do, while the red, not sensibly diminishing the brilliancy of the metal, but, on the contrary, augmenting the intensity of its colour, produces an excellent effect.

The green ground is more intense and bluer than the same ground upon which the painted ornaments are placed.

395. The study of the effects of red and of green grounds upon painted ornaments, on the one hand, and upon gilt ornaments on the other, is extremely interesting to paperstainers and decorators; it demonstrates to them the necessity of taking into consideration, in the juxtaposition of bodies which it is proposed to associate, the brilliancy which these bodies naturally possess, and the brilliancy we wish to impart to them, if they have none. The preceding examples (386, 394) explain why the paperstainer

will choose dark red instead of green for his gilt ornaments, and why a decorator will prefer green to red for the colour of the hangings of a show-room of gilt bronzes, gilt clocks, &c.

Blue Ground.

396. Observation agrees perfectly with the law that it is really upon a blue ground, that painted ornaments, whose dominant colour is the complementary of blue, show themselves to the greatest advantage with respect to intensity of the gold-yellow colour. This effect more than compensates for the slight difference which may result from the red ground giving a little more brilliancy. The ornaments upon the latter ground, compared with those on the blue, are less coloured and appear whiter.

With _metallic gilt ornaments_ the blue ground is deeper and less violet than with painted ornaments.

Violet Ground.

397. Conformably to the law, the violet ground giving greenish-yellow to the painted ornaments, is favourable to them; they appear on this ground less olive-grey, more brilliant than upon the white ground, and less green than upon the red ground.

Metallic gilt ornaments stand out quite as well, the ground is raised in tone, and the violet appears bluer or less red.

398. It is remarkable that gilt ornaments, compared with their painted imitations, heighten all the grounds upon which they are placed. We cannot say that this metal causes the grounds to lose their brilliancy, for orange gaining some red, by the juxtaposition of the gold, appears, nevertheless, more brilliant than the orange in juxtaposition with the painted ornaments. The gold, by its orange colour, gives also some blue, its complementary, to bodies which surround it.

2.—BORDER OF FOUR INCHES IN BREADTH PRESENTING ORNAMENTS COMPOSED OF FESTOONS OF BLUE FLOWERS, OF WHICH THE EXTREMITIES ARE HELD BY GREY LEAVES OF ARABESQUES.

Plate 16.

399. These ornaments are opposed in some respects to the preceding by their dominant colour, which is blue.

Black Ground.

400. Grey lowered three tones in comparison with grey; upon white less reddened.

Blue flowers lowered two tones at least.

Red Ground.

401. The grey is greenish, while upon white it is reddish.

The blue flowers are lowered three tones, and the blue inclines to green.

Orange Ground.

402. Grey much lowered; less red than upon white. Flowers paler, and of a blue less red or less violet, than upon a white ground.

Yellow Ground.

403. Grey higher than upon white ground, more violet.

Flowers of a more violet-blue, less green than upon a white ground.

Green Ground.

404. The grey is reddish, while upon a white ground it appears greenish.

The blue gains red or violet, but it loses much of its vivacity; it resembles some blues of the silk-vat, which, giving yellow to the water, become slaty-blue-violet.

[Illustration: PLATE XVI.]

Blue Ground.

405. The blue ground being fresher than that of the ornament, it follows that it gives _orange_ to the blue of the flowers; that is to say, it _greys_ them in the most disagreeable manner.

The grey ornament is _oranged_, and lighter than upon the white ground.

Violet Ground.

406. Grey lowered, yellowed, impoverished. Blue tends to green, and is impoverished.

3.—BORDER OF FIVE INCHES AND A HALF IN BREADTH, REPRESENTING ROSES WITH THEIR LEAVES.

Plate 17.

407. This border is particularly useful as an example of the effect of two colours, red and green, which are very common in the vegetable world, and often represented upon paper-hangings.

Black Ground.

The green is less black, lighter, fresher, and purer, and its brown tones redder than upon a white ground. With respect to its lighter tones, I see them yellower, while, on the contrary, they appeared bluer to three persons accustomed to observe colours. This difference, as I at last found, arose from my comparing the general effect of leaves upon a black ground with that of leaves upon a white ground; while the other persons instituted their comparison more particularly upon the browns and the light tones of green, placed upon the same ground. This difference in the manner of seeing the same objects will be the subject of some remarks hereafter.

Rose lighter, yellower than upon a white ground.

Dark Red Ground.

408. Green more beautiful, less black, lighter than upon a white ground.

Rose more lilac, perhaps, than upon a white ground. The good effect of the border upon this ground is due chiefly to the greatest part of the rose not being contiguous to red, but to green; because the border and the ground exhibit flowers, the rose of which contrasts with the green of their leaves; while the same green contrasts with the red of the ground, which is deeper and warmer than the colour of the flowers.

Orange Ground.

409. The green lighter, a little bluer than upon a white ground.

Red much more violet than upon a white ground.

The general effect not agreeable.

Yellow Ground.

410. Green bluer than upon a white ground.

Rose more violet, purer than upon a white ground.

The whole exhibits a good effect of contrast.

Green ground, the tone of which is nearly equal to that of the lights of the leaves, and the hue of which is a little bluer.

Green of the leaves lighter, yellower than upon a white ground.

Rose fresher, purer, more velvety than upon a white ground.

[Illustration: PLATE XVII.]

Ground of an agreeable effect from harmony of analogy with the colour of the leaves, and from harmony of contrast with the rose of the flowers.

Blue Ground.

411. Green lighter, more golden than upon a white ground.

Rose yellower, less fresh than upon a white ground.

Although the green leaves do not exactly produce a bad effect upon the ground, yet the roses lose much of their freshness, and the appearance of the whole is not agreeable.

Violet Ground.

412. Green yellower, lighter than upon a white ground.

Rose faded.

If the ground does not injure the green of the leaves, yet it injures the rose so much that it is not agreeable.

4.—BORDER OF SIX INCHES IN BREADTH, REPRESENTING WHITE FLOWERS, AS CHINA ASTER, POPPY, LILY OF THE VALLEY, ROSES; SOME RED FLOWERS, AS THE ROSE-WALLFLOWER SOME SCARLET OR ORANGE, AS THE POPPY, POMEGRANATE, TULIP; BIGNONIA AND VIOLET FLOWERS, AS LILAC, VIOLETS, AND TULIPS WITH GREEN LEAVES.

413. This border was remarkable for the pleasing combinations of the flowers among themselves, and of the flowers with their leaves. In spite of the multiplicity of colours, and of the hues of red and violet, there was no disagreeable juxtaposition, except that of a pomegranate next to a rose; but the contact only took place at one point, and the two flowers were in very different positions.

Black Ground.

414. The whole lighter than upon a white ground.

Orange finer, brighter than upon a white ground.

White the same.

Green lighter, redder. The roses and the violets gain nothing from the black.

Red-Brown Ground.

415. The whole lighter than upon a white ground.

Whites and greens of fine effect. An orange-flower contiguous to the ground, for the reason explained above (407), acquires a brilliancy which it has not upon a white ground.

Orange Ground.

416. The whole more sombre, duller than upon a white ground. Orange-flowers and roses dull, lilacs bluer.

This assortment is not good.

Yellow Ground.

417. The orange-flower contiguous to the ground evidently loses vivacity in comparison with the white ground.

The whites are less beautiful than upon a red ground.

The greens are bluer than upon a white ground.

The roses become bluer, the violets acquire some brilliancy.

The whole effect is good, because there is but little yellow in the border, and but little orange contiguous to the ground.

Green Ground.

418. The ground being fresher than the green of the leaves, had not a good effect, relatively to them. On the other hand, the green in the border was in too small a quantity to produce a harmony of analogy, and it had not sufficient red for a harmony of contrast.

Blue Ground.

419. The oranges have a fine effect, the greens were reddened as well as the whites. The roses and the lilacs lost some of their freshness.

This arrangement did not produce a good effect, because there was not sufficient yellow or orange in the border.

Violet Ground.

420. Orange more beautiful than upon a white ground.

Roses, and violets especially, less beautiful than upon a white ground. A poor assortment.

Grey Ground.

421. As might be easily foreseen, this ground was extremely favourable to all the colours of the border.

422. The examination we have just made of four sorts of borders enables us to verify the exactness of the conclusions which are directly deducible from the law of simultaneous contrast of colours, and presents to us effects which we could scarcely have deduced from the same law without the aid of experiment. I now speak—

1. Of the influence which a complementary exercises by imparting _brilliancy_ to the colour to which it is added.

2. Of the very different manner in which not only different people, but even the same person, will judge of the colours of a more or less complex pattern, having a certain number of colours, according to the attention the spectator gives at a certain moment to different parts (407).

423. Our examination of the border of roses with their leaves (No. 3), and especially of that of the border of flowers varied in their forms and hues (No. 4), shows the necessity of a knowledge of the law of contrast to assort the colours of objects represented upon a border with the colour which serves as a ground to them. The examination of the border No. 4 has demonstrated experimentally that this assortment presents so much the more difficulty as we wish to have purer tints for the ground, and more varied colours in the objects we intend placing on it; besides, in demonstrating the good effect of grey as a ground for these latter objects, it has furnished an example of a fact which may be deduced from the law, and which is in perfect accordance with what practice taught us long ago.

PRINTED OR WRITTEN CHARACTERS ON PAPERS OF DIFFERENT COLOURS.

424. Having made it a rule in this work never to state any observations which I have not myself verified, I must mention that, not possessing every requisite for the examination of the subject of this section, I am obliged to develop certain points of it only.

We must regard—

1. The duration of the reading, and

2. The kind of light which illuminates the printed or written paper.

A.—INFLUENCE OF DURATION IN THE READING.

425. From the different conditions in which the eyei s found when it is apt to perceive the phenomena of simultaneous, successive, and mixed contrasts of colours (77 _et seq._), it may be conceived that in order to judge of the effect upon the sight of the assortments of the colour of the letters and that of the paper as to the degree of facility that they respectively present for reading, it may happen that one assortment will be more favourable during a brief reading, while the contrary will take place if the reading be prolonged during several hours. Besides, an assortment presenting the greatest contrast will be more favourable to a reading of short duration, while it will be less so to a prolonged reading; because, in consequence of the intensity of its contrast, it will fatigue the eye more.[2]

[2] Hence the pleasure of reading books printed on the modern _toned_ paper. De Morgan advises that tables of logarithms, and the like, should be printed on pale brown paper.

B.—INFLUENCE OF THE KIND OF LIGHT ON PRINTED OR WRITTEN PAPER.

426. The light we employ to supply the place of that of the sun, changing the relations of colour under which the same bodies appear to us illumined by daylight, it is evident that if we neglected this difference of relation it would give rise to error; because any assortment of colours favourable to read in diffused daylight, might be less so by the light of a lamp, &c.

427. I will now examine—

The influence of different assortments of the colours of writing and printing for reading by diffused daylight.

ON THE ASSORTMENT OF COLOURS FOR READING BY DIFFUSED DAYLIGHT.

Reading of a Few Minutes' Duration.

428. Letters upon paper can be read without fatigue only when there is a marked contrast between the letters and the ground. This contrast may be of tone, or of colours, or both.

429. _Contrast of tone_ is the most favourable condition for distinct vision, if we consider white and black as the two extremes of a scale, comprehending the gradations from normal grey; in fact, black letters upon a white ground present the maximum of contrast of tone, and may be read in a perfectly distinct manner without fatigue by diffused daylight. Indeed, all whose sight is enfeebled by age require the utmost contrast of tone.

FOURTH DIVISION.

Employment of Colours in Architecture.

I. ON THE EMPLOYMENT OF COLOURS IN EGYPTIAN ARCHITECTURE.

430. The Egyptians employed various colours, as red, yellow, blue, green, and white, to decorate their monuments.

Lancret remarks, "All who have seen Egyptian paintings, can attest that when seen, even for the first time, they were not disagreeable; and, that if at first the colours appear distributed arbitrarily, it is because observers have not combined a sufficient number of observations, and that it will one day be found that this part of the arts of the Egyptians was, like all the rest, submitted to invariable rules."

431. Champollion the Younger expresses himself in these terms on the application of colours to Egyptian architecture: "I should like to introduce into the great temple of Ipsamboul, all who refuse to believe in the elegant richness that painted sculpture adds to architecture; in less than a quarter of an hour, I engage that they would perspire away all their prejudices, and that their _à priori_ opinions would quit them through every pore."

432. The fact of colouring hieroglyphics being once admitted, the colouring of the other figured objects which accompany them appears to have been a necessary consequence, either to bring out certain symbols, or allegories more distinctly and more agreeably, by the effect of their various colours, or because, if the hieroglyphics only were differently coloured, there would be no harmony between them and the other figured objects. No one can mistake the harmony between the hieroglyphics and other painted objects, and we therefore should not see any impropriety in them if we mistook them for figures traced by the capricious imagination of the artist. This harmony clearly justifies Lancret and Champollion the Younger, in the passages quoted above.

II. ON THE EMPLOYMENT OF COLOURS IN GREEK ARCHITECTURE.

433. The discovery of Greek temples coloured on the exterior is doubtless a very remarkable fact in archæology; for if any monuments seemed to reject the application of colours to their external decoration, it was assuredly those of the Greeks. At this day, it is impossible not to admit that it was among these people that the alliance of colours with architecture was made, not in the declining epoch but at a period when monuments were erected in the best style; in fact, the ruins of coloured temples discovered by the excavations made in Greece, Italy, and Sicily, in places where many Greek colonies prospered, have this characteristic in a remarkable degree.

434. If we seek the cause which determined the Greek architect to seize upon one of the most powerful means that the painter has of addressing the eye, we shall find it especially, I think, in a taste for colours, rather than in the intention of rendering the various parts of an edifice more distinct from each other; and of substituting painted ornaments for ornaments in relief, whether sculptured

or moulded, or of augmenting the relief these ornaments already possessed; indeed, the communication of the Greeks with the Egyptians, may have induced them to imitate the latter in this application of colours to ornaments.

435. In the coloured drawings of Greek monuments which I have been able to procure, I have remarked not only the number of colours employed in these monuments,—_white_, _black_, _red_, _yellow_, _green_, and _blue_,—but also the use which has been made of them under the relation of _variety_ and _purity of tint_, of _distinct view of the parts_, and of the _harmony of the whole_. For instance, the principal lines, as the fillets of the architrave and of the cornice, are _red_; the mutules _blue_, and their guttæ _white_; the triglyphs _blue_, their channels _black_, and their guttæ _white_; and the more extended parts of the frieze and the cornice, as well as the architrave, are of light _yellow_.

We see that _red_, a brilliant colour, indicated the greater part of the principal lines; that _blue_, associated with _black_ in the triglyphs and their channels, formed an harmonious and distinct union of the neighbouring parts: also that the dominant colour, light _yellow_, produced a much better effect than it would if the most intense or the most sombre colours had predominated. Finally, the colours were distributed in the most intelligent manner possible without being motley, presenting a variety and lightness in the tints, with easy separation of parts.

III. ON THE EMPLOYMENT OF COLOURS IN GOTHIC ARCHITECTURE.

436. In the great Gothic churches, colour has rarely been employed on the exterior, except in a few cases, and always in a restrained manner, and without injury to the general harmony; for the colour on porches and in niches is altogether insignificant in this point of view; and, besides, there is nothing to show that it was not added long after the erection of the structure on which it is found. One of the things I most admire in these vast edifices is the art, or, if you will, the luck, with which they have succeeded without colour, by having recourse only to architecture and sculpture, in giving to the exterior of the edifice a variety which in no respect injures the imposing effect of the whole.

437. If we now regard the interior of these churches, the magic of the colours of the stained windows will complete the enjoyments the sight can receive from colour allied to architecture—enjoyments which can only strengthen the power of the religious sentiment in all who enter these edifices to address their prayers to God. M. Boiserée, author of a work full of research, as original as profound, on the cathedral of Cologne, thinks that the ceilings of Gothic churches ought, according to a general custom, to represent the celestial vault, and be painted blue, studded with gilt stars.

438. If painting has from the beginning really concurred with architecture, and even with painted sculpture, in the interior decoration of Gothic churches, it can only have been in a secondary degree and on the system of flat tints, from the time when it had been decided to put in windows of stained glass; for no painting applied upon an opaque body, such as stone, wood, &c., could sustain itself beside the brilliant coloured light transmitted by the glass; and if this painting had been graduated according to the rules of chiaro-'scuro, all its merit would have disappeared, for want of pure and white light, the only kind suitable for illuminating it.

439. Is it true that the vicinity of stained glass necessarily requires as an effect of harmony, painting on the contiguous walls? Without deciding absolutely in favour of the contrary opinion, I confess that, after reflecting long upon the deep impressions I have received in great Gothic churches where the walls present only the simple effects of light and shade upon a uniform surface of stone, where there are no colours except those transmitted by the stained glass, I say that the sight of more varied effects would have appeared to me an error against the principle of suitability of the place to its destination; and this opinion was especially fortified by seeing, after the coronation of Charles X., the fine vault of the ancient cathedral at Rheims, which had been painted for the occasion blue, sprinkled with _fleurs-de-lis_. I am reminded of the impression it produced upon me some years before, when it presented to my sight only the uniform colour of the stone.

APPLICATION TO THE INTERIORS OF EDIFICES.

440. I shall treat in succession—

1. On the assortment of stuffs with the wood of seats, &c. 2. On the assortment of frames with the pictures, engravings, and lithographs which they surround. 3. On the general decoration of interiors of churches. 4. On the decoration of museums, galleries, &c. 5. On the decoration of houses, palaces, &c.

On the Assortment of Stuffs with the Wood of Seats.

441. There should be between the two parts of the seat—the wood and the stuff—harmony of contrast and harmony of analogy. The beauty of the wood and of the stuff which accompanies it, may mutually enhance each other. From what has been said, it is evident that we must assort violet or blue stuffs with yellow woods, as the root of ash, the yew, satinwood, maple, &c. Green stuffs with rose or red-coloured woods, as mahogany, cherry-tree, rosewood, &c.

Violet, or blue-greys, are equally good with yellow woods, as green-greys are with the red woods.

But to obtain the best possible effect it is necessary to take into consideration the contrast resulting from depth of tone; for a dark blue or violet stuff will not accord so well with a yellow wood as a light tone of the same colours; and it is for this reason that yellow does not assort so well with mahogany, as with a wood of the same, but not so deep a colour.

442. Among the harmonies of contrast of tone that can be made with wood, may be mentioned ebony, the brown colour of which permits its employment with light stuffs to produce contrasts of tone, rather than contrasts of colour. We can use it with very brilliant, intense colours; such as poppy, scarlet, aurora, flame-colour, &c.

443. When we employ painted woods instead of those which retain their natural colour, it is better for a stuff to give the wood such a colour as will best assort with the stuff. For assortments of this kind, I believe we cannot do better than refer to the examples of the assortments of the principal colours with white, black, and grey. (P. 49 _et seq._)

444. Ebony wood, on account of its dark colour, be employed with dark stuffs to produce the assortments of analogy. In this case it can be allied with brown tones, and with red, blue, green, and violet. It is scarcely necessary to remark that these assortments prevent our using with ebony, white and yellow inlaying woods, which can be used with more or less advantage in those assortments which enter into the case of harmonies of contrast.

445. Frequent use is made of crimson woollen, velvet, and mahogany. This assortment, which is related to the harmony of analogy, is preferable to many others, only in consideration of the great stability of the colour of the stuff, and therefore independently of every idea of harmony. This induces me to examine it under several relations, that we may make the best possible use of it, according to the particular purpose.

When, in assorting crimson with mahogany, we wish to produce the harmony of analogy, by marking out the lines where the wood and the stuff touch, we can employ a cord or narrow galloon of yellow, or of golden yellow with gilt nails; or, better still, a narrow galloon of green or black, according to our wish to render the border more or less prominent.

When, in assorting these colours, we are guided by the twofold motive of the stability of the crimson colour and of the beauty of the mahogany, we must necessarily increase the distance which separates the stuff from the wood, by making the black or green border wider.

446. As the red woods always lose more or less of their beauty by the juxtaposition of red stuffs, we can never ally mahogany to colours which belong to the vivid reds, such as poppy or cherry; and more particularly to orange-reds, such as scarlet aurora; for these colours are so bright, that, taking away from this wood its peculiar tint, it becomes no better than oak or black walnut.

ON THE SELECTION OF FRAMES FOR PICTURES AND ENGRAVINGS.

447. If a frame is necessary to a picture, engraving, or drawing, to isolate it from the objects around it, it is always more or less injurious to the illusion the painter or designer has desired to produce, when it occupies its destined place. I only purpose here to examine the relation of colour between the frame and the object it surrounds.

448. Gilt frames accord well with large pictures painted in oil, when the latter do not represent gildings, at least so near the frame as to render it easy for the eye to compare the painted gold with the metal itself.

I will instance a bad effect from such proximity. A Gobelins tapestry, after Laurent, represents a genius armed with a torch, near which is a gilt altar, executed in yellow silk and wool, all of which are entirely eclipsed by the metallic brilliancy of the gilt bronzes profusely spread over the mahogany frame of the tapestry. This may convince us that the richness of a frame may not only be a fault against art, but also against common sense.

449. Bronze frames which have but little yellow brilliancy do not injure the effect of an oil picture which represents a scene lighted by artificial light, such as that of candles, torches, a conflagration, &c.

450. When black frames, such as ebony, detach themselves sufficiently from an oil painting, they are favourable to large subjects; but whenever they are used, it is necessary to see whether the browns of the painting or drawing which are contiguous, do not lose too much of their vigour.

451. A grey frame is favourable to many landscape scenes painted in oil, particularly when the picture having a dominant colour, we take a grey lightly tinted with the complementary of that colour.

452. Gilt frames accord perfectly with black engravings and lithographs, when we take the precaution of leaving a certain extent of white paper round the subject.

453. To conclude. The rule to be followed in assorting a frame to a picture is, that its colour, brightness, and ornaments also, injure neither the colours, nor the shadows, nor the lights of the picture, nor the ornaments which it represents.

When we propose to put a border between the frame and an engraving, plain or coloured, we must take into consideration,—

1. The effect of the height of tone of this border upon the different tones of the design.

2. The effect of the complementary of the colour of the border upon the colour of the design.

3. The intensity of the diffused light which is considered most suitable to light the design. Because for a given border the mutual relations between the browns, the half-tints, the lights and the whites, change with the intensity of the daylight, and change more for a given composition with certain borders than with others.

A composition of small or medium size may be painted so that the artist himself will do well to choose the frame best adapted to it, and to paint up those parts of his picture which are contiguous to it. (See also 483.)

ON THE GENERAL DECORATION OF THE INTERIORS OF CHURCHES.

I now resume this subject, no longer to treat of it relatively to a given architectonic form, but to consider it under the most general point of view.

Conformably to the principle enunciated above (346), of judging the productions of art by the rules drawn from the nature of the materials employed, I establish two distinct classes of churches, not according to their form, but to a fundamental consideration which subordinates the interior decoration to the quality of the light, coloured or colourless, diffused through plain or coloured glass.

Stained Glass Windows.

1. From the bad effect of the mutual proximity of white and stained glass (365), it results that where one is employed in a church the other must be excluded, at least from the nave, choir, in a word, from all that the spectator can embrace at one point of view. The colourless glass in some of the chapels of the aisles is of no consequence in the general effect.

2. If pictures be near stained windows, they must be flat, or present subjects as simple as possible, since their effects are entirely sacrificed to those of the stained glass (438).

3. We can place pictures in a large church where the light is transmitted through coloured glass; but, for the view to be satisfactory, they must necessarily encounter such a union of conditions, that they will almost always be found out of place. In fact, if the pictures are not at a certain distance from the glass,—if the coloured lights which emanate from them are not, by their mutual admixture, in the requisite proportions for producing white light, or, at least, a very faintly coloured light—or if this feebly coloured light is insufficient to lighten the interior of the church properly, the pictures will lose their colour, unless they have been executed with reference to the nature of the light from the stained windows; but this is not, to my knowledge, ever realized.

White Glass Windows.

454. Churches with white glass windows harmonize with every ornament we can imagine in the employment of wood, marbles, porphyry, granite, and the metals. Mosaics may ornament the floors and adorn the walls with true pictures, as we see in St. Peter’s at Rome. Painting in fresco, in oil, plain and coloured sculptures, also combine to ornament the interior.

1. In churches of this class, the profusion of riches at the disposal of the decorator, far from being always of advantage to him, may be the cause of difficulties; for, the more varied the objects he has to arrange, the greater the difficulty of presenting only such

objects as are in keeping with the place he has to embellish. It is not enough to have precious woods, marbles, metals, pictures; he must also make these objects harmonize. Thus, he must avoid putting coloured marbles contiguous to the white stone of which the walls are constructed; he must also proscribe surrounding bas-reliefs in white stone with slabs or borders of red or green marble.

2. The cathedral of Cologne, for churches with _coloured_ glass, and St. Peter's at Rome, for those with _white_ glass, are two types which it will be sufficient to mention when we wish to demonstrate that beauty is compatible with different systems.

3. Much as I admire the marvels which the arts have accumulated in churches where white light freely enters, and although I acknowledge the effects which certain pictures of the first order are capable of producing in the Christian mind, yet the churches in which we see these decorations, resemble museums of art more than temples consecrated to prayer; and under this aspect they do not appear to me to fulfil the conditions imposed by the principle of fitness of edifices to their purpose in the same degree as Gothic churches with stained glass windows.

ON THE DECORATION OF MUSEUMS AND GALLERIES.

455. The essential condition which these edifices must fulfil, is, that the light be as white and as vivid as possible; but always diffused and distributed equally and in the most suitable manner upon all the objects exhibited to the spectator, so that they may be seen without fatigue, and distinctly in every part.

Picture Galleries.

456. There is generally a disposition to be prodigal of ornaments and gilding in such buildings. Without pretending that all decoration should be proscribed, yet I believe that there is less disadvantage in erring by deficiency than by excess; in fact, the pictures, &c., are the precious objects, and it is to them that we must attract attention. Let me add, that one of the most injurious things to the effect of pictures is their accumulation—their being crammed all together; the position they then occupy, so different from that for which the painters destined them, diminishes the illusion which each would produce if it were in its proper place. Few, except the intelligent connoisseur and amateur, on seeing a picture exhibited in a gallery, experience all the effect which the artist wished to produce. Even the contiguity of the frame to the picture is destructive of the illusion of perspective: hence the difference between the effect of a framed picture and the effect of the same picture when seen through an opening, which permits us to see neither frame nor limits: it then recalls all the illusion of the diorama.

Sculpture Galleries.

457. Statues of white marble or stone, as well as plaster casts, stand out well in a gallery, the walls of which are of a pearly-grey colour; and if we would augment the whiteness of the statues by neutralizing the red hue which the marble, stone, or plaster might have, we could colour the walls with a chamois or orange-grey tint. If, on the contrary, we preferred giving to the statues a warm colour, which many sculptors esteem so highly, the walls must be of blue-grey. Green walls will give to the statues a rosy tint, which is not disagreeable.

The tone of their colour must be lower, the brighter we wish the sculptures to be.

458. When there are bronzes, the colour of the walls of the gallery must be determined by that which we wish to predominate in the statues; because, as is very well known, the metallic alloy of which they are formed yields two very different tints; one _green_, acquired by exposure to atmosphere; the other the peculiar _golden_ tint which it possesses where it is not oxidized. If we wish to exalt this green tint, the colour of the walls of the gallery must be _red_; while they must be _blue_ to bring out the brilliancy of the metallic bronze, which has not experienced the action of the atmosphere.

459. The walls of the gallery are considered as giving rise to effects of contrast, and not of reflection.

Museums of Natural History.

460. In these edifices it would be wrong to give the walls any positive colour, for the objects exhibited should appear to the eyes of the naturalist of the colour peculiar to each; consequently the interior of cabinets, glass-cases, and drawers must necessarily be white, or normal grey, very light in tone.

Wainscoting.

461. From the fact that wainscotings are generally concealed by the furniture placed before them, we may conclude that they must be of a dark, rather than of a light colour, and that, if they have ornaments, these must be simple, and not prominent. The wainscoting may be considered as serving as a ground to the furniture, whenever it is not entirely concealed by the latter. We shall see hereafter what colour is necessary to be given them that they may suit their purpose.

DECORATIONS OF THE INTERIOR OF HOUSES.

Hangings.

462. In consequence of an apartment never being too light—for we can always diminish superfluous light—hangings should be of a light colour, that they may reflect, not absorb, light.

463. We proscribe all dark hangings, whatever be their colour, because they absorb too much light; we proscribe also red and violet hangings, because they are exceedingly unfavourable to the colour of the skin. For this latter reason we reject the light tones of the red and violet scales. Orange is a colour that can never be much employed, because it fatigues the eye too much by its great intensity.

1. Among the simple colours, there are scarcely any which are advantageous, except yellow and the light tones of green and of blue. Yellow is lively; it combines well with mahogany, furniture, but not _generally_ with gilding (see 469).

2. Light green is favourable to pale complexions as well as to rosy ones; to mahogany furniture, and to gilding.

3. Light blue is much less favourable than green to rosy complexions, especially in daylight; it is particularly favourable to gilding, it does not injure mahogany, and associates better than green with yellow or orange woods.

4. White or whitish hangings of a light grey (either normal green, blue, or yellow), uniform or with velvet patterns of the colour of the ground, are also very useful.

5. When we would choose hangings upon which to place a picture, their colour must be uniform, and make the greatest contrast possible with that which predominates in the picture, if the hangings are not of a normal grey. I shall return to this assortment (483).

464. Hangings in the best taste are those—

1. Which present designs of a light tone, either normal or coloured grey, upon a white ground, or the reverse, and in which the pattern is at least equal in extent of surface to the ground; for a small pattern has a very poor effect, at least in a large room.

2. Patterns of two or more tones of the same or very near scales assorted conformably to the law of contrast.

465. Hangings of brilliant and varied colours representing real objects, forming patterns more or less complex, do not admit of pictures; and as such hangings should exhibit themselves distinctly, they must not be concealed by the furniture in any of their parts.

466. When we have to adapt a border to a monochromous hanging, or to one presenting a dominant colour, we must first determine whether we can have recourse to a harmony of analogy or to a harmony of contrast; in all cases the border ought to detach itself more or less from the hangings, which it is intended to surround and separate from contiguous objects.

Harmony of contrast is the most suitable to papers of a uniform pure colour, such as yellows, greens, and blues; consequently we recommend for the dominant colour of the border, the complementary of that of the hangings, whether this border represents ornaments, arabesques, flowers, or imitations of fringes or tissues. But, as a contrast of colour ought not generally to offer also a contrast of tone, then the general tone of the border must only surpass that of the hangings so far as to avoid a deadening effect. If a double border be required, the exterior border must be of a much deeper tone than the other, and always narrower.

467. Among the colours suitable for borders we recommend the following as harmonies of contrast:—

1. For yellow hangings, violet and blue mixed with white; if a fringe, of flowers garnished with their leaves, or ornaments.

2. For green hangings, red in all its hues; the painted gilt-yellows upon a dark-red ground; the borders of brass.

3. For white hangings, orange and yellow; the borders of brass or gilt moulding: these are much better on blue than on green.

468. Among the harmonies of analogy, I recommend the following:—

For yellow hangings, a border of brass or gilt moulding.

White or Whitish Hangings of Normal Grey, Pearl Grey, or very pale coloured Grey, of a uniform colour, or with a Velvet Pattern of the Colour of the Ground.

469. Although papers of this kind admit of borders of all colours, yet we must avoid too great a contrast of tone in a border containing pure colours; for the intense tones of blue, violet, red, green, are too crude to combine with these light grounds. Gilt brass borders accord well with these grounds, especially with the pure or grey whites. If a grey present a tint of green, of blue, or of yellow, we may use borders of the complementary of these tints, taken many tones above, or of a grey, deeply tinged with this complementary.

470. Among the harmonies of analogy, we may take for grey hangings, borders of some tones higher, and of a grey contrasting with their tint, but very lightly.

For Borders of Hangings that present a pure Colour with White, or many Tones belonging either to the same Scale or to contiguous Scales (see 466).

For _chintzes_, we must have analogous borders.

For larger patterns than chintzes, repeated like the latter, a binding of galloon suffices.

Hangings with human figures, landscapes, or other pictures, require a frame either of painted, gilt, or bronzed wood, or, better still, a border imitated by painting.

Colour of the Wainscoting relatively to the Hangings.

When the Hangings and the Border make a Contrast of Colour.

471. The dominant colour of the wainscoting must generally be more or less approximating, and may be—

1. The same as that of the border, but a little darker, and especially more or less broken with black.

2. Grey lightly tinted with the colour of the border, and of the same tone, or very near it.

3. The complementary of the colour of the hangings, when the dominant colour of the border is not its complementary. If we employ a complementary lightly broken with black, the moulding must be picked out in brown on the border and on the wainscoting.

4. A grey complementary to the colour of the hangings, when the border is not the complementary of the hangings.

In these cases we bring out upon the colour of the hangings, properly so called, that of the wainscoting, which we always render more or less dull. Thus the colour of the hangings and the wainscoting are agreeably harmonized, and the border suitably separates them.

5. A normal grey of many tones, with which we may combine white.

472. When the colour of the wainscoting is the same as that of the hangings, but duller or deeper, in general it has a poor effect, arising particularly from the fact that the colour of the border, which contrasts with that of the hangings and of the wainscoting, is in too small superficial proportion to the other.

When the Assortment of the Hangings and the Border make either the Harmonies of Contrast of Scale or of Contrast of Hue, or the Harmonies of Analogy.

The dominant colour of the wainscoting may be—

1. The complementary of the colour of the hangings, but more or less broken, and a little deeper.

2. Grey complementary to the colour of the hangings.

3. A colour which, without being complementary, contrasts with that of the hangings.

4. Grey, tinted by a colour which, without being complementary to that of the hangings, contrasts with them.

473. When the hangings are white, or of an extremely feeble tone of colour, and the border does not stand out very strongly by its colour, we may make a harmony of tone or of hue with the tint of the wainscoting. For example, white, or nearly white hangings, with a gilt or brass border, harmonize well with a wainscoting which differs only by some tones more from the colour of the hangings.

Cornice of the Ceiling.

474. The cornice of a white ceiling must be of light colours, and but little varied; not according with those of the hangings, but of the wainscoting. White parts, which may be confounded with the ceiling, must be carefully avoided, as must also whatever will cause too much difference between the parts of the whole. When the hangings are white, or of a very pale grey, with a gilt or brass border, the cornice may present ornaments of the same material, and in this case they may stand upon a white or upon a grey, a little deeper than that of the hangings.

Chairs, Sofas, &c., placed in front of the Wainscoting or Hangings.

475. The colour of the covering of chairs should be complementary to that of the hangings, properly so called, or, more generally, the same as that of the border, because this may be different from its complementary, and contrast, nevertheless, with the tint of the hangings. We see, then, that the chairs should contrast with the hangings, as may also the wainscoting; but the colour of the chairs being pure, it will also be purified by that of the wainscoting, which, for this reason, we have advised to be deadened.

1. The case of clearest contrast—_i.e._, when the colours of the hangings and the chairs are complementary—is the most favourable to distinct vision, as well as to successive contrast, whenever we observe first the hangings separately, and afterwards the chairs separately, and _vice versâ_.

2. When the colour of the hangings and of the chairs contrast without being complementary, we must take into consideration the degree of _light_ in the colour of the hangings. For example, if they are blue, and the border is yellow, the covering of the furniture being a yellow, more golden than citron, this stuff must be of a much higher tone than the blue tone of the hangings; and the tone of the wood of the chairs, &c., must be still higher than the yellow, to avoid a dull appearance.

3. We may border the stuff at the parts contiguous to the wood, either with well-assorted dark colours, or with the same colour as the hangings, but of a higher tone; there is also a means of harmonizing the hangings and the furniture, in uniting the same colours, but in inverse proportion.

4. When, instead of sofas, arm and other chairs, there is a _divan_ which entirely conceals the wainscoting, we must use the complementary colour of the hangings, when it is more advantageous for the colour of the border to form a contrast of scale or of hue with the hangings. In this case, yellow hangings bordered with brass in relief with a violet-coloured divan, will produce an excellent effect, at least by daylight; for we must not forget that yellow and violet lose in artificial light.

5. We regard as a harmony of contrast of colour light hangings of a pure colour with furniture of a grey, tinted with the complementary to that of the hangings.

476. Rooms differing in dimensions, according as they belong to the lively or grave harmonies, will be adapted to very different purposes.

1. In small rooms—such, for example, as boudoirs, where the hangings are bright—a harmony of contrast of hue, of scale, or a harmony of analogy, is generally preferable to a harmony of contrast of colour, if the hangings are uniform, or have a dominant colour. If they have a decided colour allied to white, or if they present patterns of various colours, such as _chintzes_, the furniture most suitable will be a divan of the same material as the hangings; and it is conformable with the object of boudoirs, or of similar places, to diminish their apparent extent to the eye, by employing only one material for the hangings and the chairs, instead of seeking to fix the eye upon distinct objects.

2. In large rooms there is an arrangement of good effect—viz., white, or very light grey hangings, with furniture of a pure colour, such as red, yellow, green, blue, and violet. When we employ these pure colours, we must heighten the tone only so much as to avoid a faded appearance. Sky-blue is the most suitable for this arrangement; crimson, which is also employed, is too harsh, especially if the room is neither very large nor well lighted.

477. _Grave Assortments_ are adapted to places devoted to quiet meetings, such as libraries, museums, studies, &c. In general, the smaller the place, or the less space there is to receive the hangings, the more the assortment must be that of a harmony of analogy.

The hangings or the pictures must present only normal grey, or a grey of a colour more or less broken; the chairs must be black or of a dark grey, either normal or coloured; and in this case we can take a grey tinted with the complementary of the colour of the grey of the hangings. If more contrast is desired, we can have recourse to the brown tones of this complementary of the colour, which tints the grey of the hangings.

478. _Window and Bed-curtains_ should be similar to each other.

When the Chairs have a decided Colour—such as Red, Yellow, Green, Blue, or Violet—the hangings should be of a pure colour, contrasting favourably with that of the chairs.

The curtains should generally be of the colour of the chairs, and their borders of the colour of the hangings, or of the colour of the hangings bordered with the colour of the chairs.

The Chairs being Grey, or of a very subdued Colour, and the hangings of a decided colour, the curtains should be either,—1. Of the colour of the chairs, with a border of the colour of the hangings: or, 2. Of the complementary of the hangings, or contrasting favourably with them; the colour of the border should be that of the hangings.

The Hangings being of a Grey Colour, or White, the curtains should be,—1. Of the colour of the chairs: or, 2. Of a pure colour, complementary to the grey of the hangings, if the latter do not belong to the scale of normal grey.

479. _Doors._—Doors being, by their use, size, and position, relatively to the plane of the wall, absolutely distinct from the wainscoting, should be distinguished from it by their colour, notwithstanding the contrary practice of painters, who make them the same. Their different parts might be painted in many low tones of the same, or of approximating scales, and always according to the harmony of analogy, as the parts of one object are concerned. The colour of the doors should be of normal grey, or of a grey tinged with the colour of the hangings or of its complementary, which will thus always unite with the hangings, either by harmony of analogy, or by harmony of contrast. The door frames should be darker than the door itself.

480. _Window Frames_ should be like the doors, according to a rule which has long been generally observed. The fastenings must be black, bronzed, or of brass.

Carpets.

481. Whatever may be the dominant colours of the subjects represented in their central part, with regard to brilliancy and contrast, they should always be separated from the chairs by a sufficient interval to prevent discord with the colour of the latter.

1. The more numerous and vivid the colours are, the more we must control their brilliancy; and the carpet most suitable will be one of simple colours and pattern. In many cases, an assortment of green and black will have a good effect.

2. If the furniture is of a single colour, or of many tones, either of the same colour or of approximating scales, we can, without disadvantage, employ a carpet of brilliant colours, and thus establish a harmony of contrast between them and the dominant tint of the furniture.

482. But if the furniture is of mahogany, and we wish to bring out its colour, then we must not have either red, scarlet, or orange as a dominant colour in the carpet.

In short, to get the best effect of the colours of the furniture, in the first case, the colours of the carpet, more or less sombre, must enter into the harmonies of analogy; while in the second, where harmony of contrast of colour does not exist in the furniture, we can, if we choose, have recourse to this harmony in the carpet without ill effect.

Pictures (See 453).

483. Whenever pictures are placed on hangings, the latter must be of a single colour, or of two very similar colours or tones of the same scale. The pattern of these hangings must be as simple as possible. Whenever a picture is placed on coloured hangings, we must always take care that the dominant colour of the hangings be complementary to the dominant colour of the picture.

Engravings and plain lithographs must never be placed beside oil paintings, or even coloured drawings.

Pearl grey, or rather deep normal grey, is a good tint to receive engravings and plain lithographs in gilt or yellow wood frames.

484. Yellow hangings can receive with advantage landscapes, in which green grass, and leaves, and a blue sky predominate. The most suitable frames in this case are those of violet ebony, or wood painted grey or black. Gilt frames have not a bad effect on the picture; but the gold of the frame and the yellow of the hangings do not contrast sufficiently to most eyes.

485. Oil-paintings in gilt frames have a good effect on hangings of olive-grey more or less deep, according to the tone of the picture. Carnations and the gold assort well on a similar ground. Papers of a deep green, and even of a deep blue, may also be advantageously employed in many cases.

ON THE ASSORTMENT OF COLOURS IN INTERIORS, THE WALLS OF WHICH ARE PANELLED OR COVERED WITH MARBLE, STUCCO, OR PAINTED WOOD.

Panelled Interiors.

486. Notwithstanding the present taste for decorations, which it is so easy to satisfy by means of paper-hangings, woven fabrics, and other accessories, I think there are in large suites of apartments two rooms for which a paneling more or less finished is very suitable; these are the dining and the billiard rooms; the scene being, as it were, concentrated on the dining or billiard tables, there is no reason to distract the attention by clothing the walls with ornaments. Where an interior is paneled, the floor should be in parquetry; a pavement of tiles, stones, or marbles would be out of keeping.

487. The colour of the curtains, for paneled interiors, must be chosen conformably to the preceding principles. For example—

White curtains will heighten the tone of the woodwork;

Blue curtains will bring out the golden tint of many woods, especially of polished oak.

Interiors covered with Marbles.

488. We can arrange marbles together on the principle of harmony of contrast or of harmony of analogy. Bronze adapts itself to them very well. If granite and porphyry are to be added, the lower courses must be composed of the latter.

Blinds are preferable to curtains, which are not suited to marbles.

Interiors covered with Wood painted of several Colours.

489. The painting on a wainscot which is not beautiful enough to be seen uncovered has for its object the imitation—1. Of hangings; 2. Of wood more or less costly; 3. Of marble.

490. When we decorate walls of a pale grey ground, which require to be warmed with arabesques, we must endeavour to imitate pictures rather than mosaics.

491. The more carefully arabesques are executed, the more variety they will present in their forms and colours, and the less they should resemble the draperies, with which they are associated. Thus, white curtains with a simple and ample border, or curtains of a slightly-elevated tone of colour, or of an extremely simple design, should have the preference to curtains which are related to arabesques by their vivid colours, their varied patterns, or striking colour; in short, the colour of the curtain, if it has any, must be sacrificed to that of the arabesques.

FIFTH DIVISION.

CLOTHING.

492. In explaining the applications of the law of contrast to the colours of Male Clothing, my intention is to discuss principally the question of the combination of colours in military uniforms as a matter of State economy; and, in the case of Female Clothing, the combinations which are most suitable for a portrait. The first question is entirely one of administrative economy; the second belongs solely to the domain of art.

I shall attain my end if, in the views set forth, the portrait-painter find the means of selecting associations of colours which, by imparting to his works more brilliancy and harmony, render them thereby less likely to appear antiquated when the prevailing fashion of his time is forgotten.

I. _Men’s Clothing._

493. A dress composed of cloths of different colours may be worn much longer, and will appear better, although nearly worn out, than a suit of a single colour, even when the latter is of a piece of cloth identical with one of the first. The law of contrast fully gives the reason of this fact.

OF THE ADVANTAGES OF CONTRAST, CONSIDERED WITH REGARD TO THE APPARENT CLEANLINESS OF CLOTHS FOR CLOTHING.

494. Contrast in the colours of cloths composing a dress is not only advantageous to the brightness and _apparent preservation_ of the colours of these cloths, but also to render less visible the inequalities which a cloth presents on account of the colouring material not having equally penetrated to the centre of the stuff; the surface wearing unequally, according as it is exposed to different degrees of friction, the colour of the cloth becomes lighter, or, as it is commonly called, _whitens_, in the parts most exposed to friction. Many blue, scarlet, and madder-red cloths present this result, especially on the salient parts of the vestment, such as the seams.

495. This defect which certain cloths have of _whitening in the seams_ is much less apparent in a coat of two or more colours than it is in a monochromous coat; because _the vivid contrast of different colours, fixing immediately the attention of the spectator, prevents the eye from perceiving the inequalities, which would be visible in a monochromic coat_.

For this reason stains, on the same ground, will always be less apparent in a polychromous than in a monochromous garment or dress.

496. For the same reason also a coat, waistcoat, and trousers of the same colour cannot be worn together with advantage, except when new; for when one of them has lost its freshness, by having been more worn than the others, the difference will be increased by contrast. Thus new black trousers worn with a coat and waistcoat of the same colour, but old and slightly _rusty_, will bring out this latter tint, while at the same time the black of the trousers will appear brighter. White trousers or reddish-grey will correct the defect. We see, then, the advantage of having a soldier’s trousers of another colour than his coat, especially if, wearing this coat all the year, he only wears trousers of the same cloth during winter. We see also why white trousers are favourable to coats of every colour.

II.—_Female Clothing._

497. Although there are many varieties of the human race with respect to the colour of the skin, yet we may arrange them in the three following divisions:—The Caucasian, or white race; the American Indians, whose skin is red or copper-coloured; the negro race, the Malays, &c., who have black or olive skins.

Colours for the Dress of Women with White Skins.

498. To give precision to this subject, we must begin by establishing certain distinctions.

1. That of the two types, with skins more or less white and rosy:—

The one with light hair and blue eyes. The other with black hair and black eyes.

2. That of the juxtaposition of the articles of the toilet, whether pertaining to the hair or to the complexion; for a colour may contrast favourably to the hair, yet produce a disagreeable effect with the skin.

3. That of the modifications of the complexion, by coloured rays emanating from the head-dress, and which, being reflected on the skin, tinge it with their peculiar colour.

499. The colour of light hair being essentially the result of a mixture of red, yellow, and brown, we must consider it as _a very pale subdued orange-brown_; the colour of the skin, although a lower tone, is analogous to it, except in the red parts. Blue eyes are really the only parts of the fair type which form a contrast of colour with the whole; for the red parts produce, with the rest of the

skin, only a harmony of analogy of hue, or at most a contrast of hue, and not of colour; and the parts of the skin contiguous to the hair, the eyebrows, and eyelashes, give rise only to a harmony of analogy, either of scale or of hue. The harmonies of analogy, then, evidently predominate in the fair type over the harmonies of contrast.

500. The type with black hair shows the harmonies of contrast predominating over the harmonies of analogy. The hair, eyebrows, eyelashes, and eyes, contrast in tone and colour, not only with the white of the skin, but also with the red parts, which in this type are really redder, or less roseate, than in the blonde type; and we must not forget that a decided red, associated with black, gives to the latter the character of an _excessively deep_ colour, either blue or green.

Of the Colours of the Hair and Head-dress.

501. The colours which are usually considered as assorting best with light or black hair, are precisely those which produce great contrasts; thus, sky-blue, known to accord well with blondes, is the colour that approaches the nearest to the complementary of orange, which is the basis of the tint of their hair and complexions. Two colours, long esteemed to accord favourably with black hair—yellow, and red more or less orange—contrast in the same manner with them. Yellow and orange-red, contrasting by colour and brilliancy with black, and their complementaries, violet and blue-green, in mixing with the tint of the hair, are far from producing a bad result.

Of the Colours of the Complexion and the contiguous Drapery.

502. The juxtaposition of drapery with the different flesh tints of women offers to portrait-painters a host of remarks, which are all the results of the principles already laid down. We shall state the most general: thus—

503. ROSE-RED cannot be put in contrast with even the rosiest complexions without causing them to lose some of their freshness. _Rose-red_, _maroon_, and _light crimson_ have the serious disadvantage of rendering the complexion more or less green. This is shown in the following experiment:—

Place two sheets of paper of either of the above colours beside two sheets of flesh-coloured paper, when it will be seen how much they are mutually injured, the lighter becoming greenish, and the darker rather of a violet hue. By substituting light green for the red, we shall find them mutually heightened and improved. The height of tone of the green influences the result: a very deep green, acting by contrast of tone, so enfeebles the complexion, that the slight contrasts of its colours will be inappreciable; a deep red, by contrast of analogy, blanches the complexion. It is necessary, then, to separate the rose from the skin, in some manner; and the simplest manner of doing this, is to edge the draperies with a border of _tulle_, which produces the effect of grey by the mixture of white threads, which reflect light, and the interstices, which absorb it; there is also a mixture of light and shade, which recalls the effect of grey, like the effect of a casement-window viewed at a great distance. Dark red is less objectionable for certain complexions than rose-red, because, being higher than the latter, it tends to impart whiteness to them in consequence of contrast of tone.

504. DELICATE GREEN is, on the contrary, favourable to all fair complexions which are deficient in rose, and which may have more imparted to them without disadvantage. But it is not as favourable to complexions that are more red than rosy; nor to those that have a tint of orange mixed with brown, because the red they add to this tint will be of a brick-red hue. In the latter case a dark green will be less objectionable than a delicate green.

505. YELLOW imparts violet to a fair skin, and in this view it is less favourable than the delicate green.

To those skins which are more yellow than orange it imparts white; but this combination is very dull and heavy for a fair complexion.

When the skin is tinted more with orange than yellow, we can make it rosy by neutralizing the yellow. It produces this effect upon the black-haired type, and it is thus _that it suits brunettes_.

506. VIOLET, the complementary of yellow, produces contrary effects; thus it imparts some greenish-yellow to fair complexions. It augments the yellow tint of yellow and orange skins. The little blue there may be in a complexion it makes green-violet. This, then, is one of the least favourable colours to the skin, at least when it is not sufficiently deep to whiten the skin by contrast of tone.

507. BLUE imparts orange, which combines favourably with white, and the light flesh tints of fair complexions, which have already a more or less determined tint of this colour. Blue is thus suitable to most blondes, and in this case justifies its reputation.

It will not suit brunettes, since they have already too much of orange.

508. ORANGE is too brilliant to be elegant; it makes fair complexions blue, whitens those which have an orange tint, and gives a green hue to those of a yellow tint.

509. LUSTRELESS WHITE, such as cambric muslin, assorts well with a fresh complexion, of which it relieves the rose colour; but it is unsuitable to complexions which have a disagreeable tint, because white always exalts all colours by raising their tone; consequently it is unsuitable to those skins which, without having this disagreeable tint, very nearly approach it.

510. VERY LIGHT WHITE draperies, such as muslin or lace, appear more grey than white. (See 503.) We must thus regard every white drapery which allows the light to pass through its interstices, and which is only apparent to the eyes by the surface opposed to that which receives incident light.

511. BLACK draperies, by lowering the tone of the colours with which they are in juxtaposition, whiten the skin; but if the vermilion, or rosy parts, are somewhat distant from the drapery, it will follow that, although lowered in tone, they appear relatively to the white parts of the skin contiguous to the same drapery, redder than if not contiguous to the black. This effect is analogous to that mentioned (385).

The Head-dress in relation to the Coloured Rays which it may reflect upon the Skin.

512. The effect of coloured bonnets on the complexion can now be readily understood; and whether it is true, as is generally believed, that a rose-coloured bonnet gives a rose tint to the skin, while a green bonnet gives a green tint to it, in consequence of the coloured rays which each of them reflects upon it, it is no longer a question about those head-dresses which, being too small or too much thrown back to give rise to these reflections, can only produce the effects of contrast, as I have said above, when treating of the juxtaposition of coloured objects with the hair and skin (501, _et seq._)

513. If an object in relief is illuminated exclusively by a coloured light, it will appear tinted with the colour of this light. A white plaster figure, for example, placed in an enclosure where the red rays illuminate it, will appear red, at least to most eyes, and under most circumstances; for certain eyes, in some cases, may perceive the sensation of the complementary of the coloured rays in looking at some parts of the figure.

514. But if the figure is placed so as to receive, at the same time, coloured rays and diffused daylight, there will be produced on the eyes of a spectator, suitably placed, a complex effect; resulting—

1. From some parts of the figure being white, reflecting to the eyes of the spectator the coloured rays falling from above.

2. From some parts of the figure reflecting diffused daylight in sufficient quantity to appear white, or almost white.

3. From there being between the parts which reflect coloured light to the eye, and those which send diffused daylight, some parts in a condition which appears to be complementary to the reflected coloured light.

515. One very remarkable consequence of this is, that the rays of mutually complementary colours, successively lighting the same object, concurrently with the diffused daylight, give rise to _the same coloration_.

516. This may be proved thus:—Between two windows directly opposite to each other, admitting diffused daylight, place a white plaster figure in such a position that each half shall be lighted directly by only one of the windows. On completely intercepting the light of one of the windows, and hanging a coloured curtain before the other, the figure appears only of the colour of the curtain; but if we open the other window, so that the figure is lighted by diffused daylight, while it is at the same time lighted by the coloured light, we then perceive some parts white, and some parts tinted with the complementary of the coloured light transmitted by the curtain.

517. This experiment, then, teaches us, that if a bonnet, rose-coloured, for example, give rise to a reflection of this colour on a complexion, the parts thus made rosy by the effect of contrast, themselves give rise to green tints, since the figure, while it receives rosy reflections, receives also diffused daylight.

518. To consider the real influence of the bonnet, we place three white plaster casts of the same model in a position equally illuminated by daylight; then observe them comparatively, after having clothed the middle cast with a white bonnet, and the two others with bonnets of which the colour of one is complementary to that of the other. _In this way we may satisfy ourselves that the

influence of reflection in colouring a figure is very feeble, even when the bonnet is placed in the most favourable manner for observing the phenomenon._

519. _Rose-coloured Bonnet._—Rose colour reflected upon the skin is very feeble, except on the temples; wherever the rosy parts are contiguous to parts feebly lighted by daylight, the latter will appear very lightly tinged with green.

520. _Green Bonnet._—Green colour reflected upon the skin is very feeble, except on the temples; wherever the green parts are contiguous to parts feebly lighted by daylight, the latter will appear slightly rosy; the effect of green in colouring it rose, is greater than the effect of reflected rose in colouring it green.

521. _Yellow Bonnet._—Yellow colour reflected upon the skin is very feeble, except on the temples; wherever the yellow parts are contiguous to parts feebly illuminated by daylight, the latter will appear very sensibly violet.

522. _Violet Bonnet._—Violet colour reflected on the skin is very feeble, even on the temples; wherever the violet parts are contiguous to parts feebly illuminated by daylight, the latter will appear slightly yellow; but this coloration is very feeble, because the reflections of violet have it themselves.

523. _Sky-blue Bonnet._—Blue colour reflected on the skin is very feeble, except on the temples; wherever the blue parts are contiguous to parts feebly illuminated by daylight, the latter will appear slightly orange.

524. _Orange Bonnet._—Orange colour reflected on the skin is very feeble, except on the temples; wherever the parts are contiguous to parts feebly illuminated by daylight, the latter will appear slightly blue.

525. It is evident, then, from these experiments, that a coloured bonnet produces much more effect by virtue of contrast, arising from juxtaposition with the flesh tints, than by the coloured reflections which it imparts to them.

526. Let us now see what advantage the painter can derive from the preceding observations, when he prescribes a bonnet to a model, belonging either to the light-haired or to the black-haired type.

FAIR-HAIRED TYPE.

527. A black bonnet with white feathers, with white rose or red, suits a fair complexion.

528. A _lustreless white bonnet_ does not suit well with fair and rosy complexions. It is otherwise with bonnets of gauze, crape, or lace; they are suitable to all complexions. The white bonnet may have flowers, either white, rose, or particularly blue.

529. A _light blue bonnet_ is particularly suitable to the light-haired type; it may be ornamented with white flowers, and in many cases with yellow and orange flowers, but not with rose or violet flowers.

530. A _green bonnet_ is advantageous to fair or rosy complexions; it may be trimmed with white flowers, but preferably with rose.

531. A _rose-coloured bonnet_ must not be too close to the skin; and if it is found that the hair does not produce sufficient separation, the distance from the rose colour may be increased by means of white, or green, which is preferable. A wreath of white flowers in the midst of their leaves has a good effect.

532. I shall not advise the use of a light or deep red bonnet, except when the painter desires to diminish too warm a tint in the complexion.

533. Finally, the painter should never prescribe either yellow or orange-coloured bonnets, and be very reserved in the use of violet.

TYPE WITH BLACK HAIR.

534. A _black bonnet_ does not contrast so well with the general appearance of the type with black hair as with the other type, yet it may produce a good effect, and receive advantageously accessories of white, red, rose, orange, and yellow.

535. A _white bonnet_ demands the same notice as that, concerning its use, in connexion with the blonde type (528), except that for brunettes it is better to give preference to accessories of red, rose, orange, and yellow, rather than of blue.

536. Bonnets _of rose-red or cherry-colour_ are suitable for brunettes, when the hair separates, as much as possible, the bonnet from the complexion. White feathers accord well with red; and white flowers, with abundance of leaves, have a good effect with

rose.

537. A _yellow bonnet_ suits a brunette very well, and receives with advantage violet or blue accessories. The hair must always interpose between the complexion and the head-dress.

538. It is the same with bonnets of an _orange_ colour, more or less broken, such as chamois, with which blue trimmings are eminently suitable.

539. A _green bonnet_ is suitable to fair and light rosy complexions, rose-red or white flowers are preferable to all others.

540. A _blue bonnet_ is only suitable to a fair or light-red complexion; nor can it be allied to such as have a tint of orange-brown. When it suits a brunette, it may take with advantage yellow or orange trimmings.

541. A _violet bonnet_ is always unsuitable to every complexion, since there are none to which the addition of yellow will be favourable. Yet, if we interpose between the violet and the skin, not only the hair, but also yellow accessories, a bonnet of this colour may become favourable.

542. Whenever the colour of a bonnet does not realize the intended effect, even when the complexion is separated from the head-dress by large masses of hair, it is advantageous to place between the latter and the bonnet certain accessories, such as ribbons, wreaths, and detached flowers, &c., of a colour complementary to that of the bonnet, as I have prescribed for the violet bonnet. The same colour must also be placed on the outside.

ON THE ASSORTMENT OF COLOURS IN THE DRESS OF WOMEN WITH COPPER-COLOURED SKINS.

543. The tint of the complexions of the women of the North American Indian races is too positive to induce them to endeavour to dissimulate, either by lowering its tone, or by neutralizing it. There is, then, no alternative but heightening it, for which purpose we must use draperies either of white or of blue strongly inclining to green, when the tint will become of a redder orange.

ON THE ASSORTMENT OF COLOURS IN THE DRESS OF WOMEN WITH BLACK OR OLIVE SKINS.

544. If I have prescribed the harmony of contrast of tone where the colour of the complexion is copper-red, there is a stronger reason for it when we have to drape olive or black skins; we can then use either white or the most brilliant colours, as red, orange, and yellow. The consideration of contrast determines which one we ought to choose in a particular case. If the complexion is intense black, dark olive, or greenish-black, red is preferable to every other colour; if the black is bluish, then orange is particularly suitable. Yellow will best accord with a violet-black.

545. _Results applicable to Portrait painting._

The tint may be heightened without leaving its scale:—

1. By a white drapery which heightens by contrast of tone. 2. By a drapery the colour of which is exactly the complementary of the tint, and of which the tone is not too high; such as perhaps a green drapery for a rosy complexion; or perhaps a blue drapery for the orange complexion of a blonde. The tint may be heightened by making it leave its scale:— 1. By a green drapery of a light tone upon an orange complexion. 2. By a blue drapery of a light tone upon a rosy complexion. 3. By a yellow, canary, or straw-coloured drapery, upon an orange complexion, of which the complementary violet neutralizes some of the yellow of the complexion, and heightens its rose.

546. _Note._—The modifications resulting from the juxtaposition of parts diversely coloured are much more positive than those arising from reflection by one part upon another.

If the Painter wishes to dissimulate a Tint of the Complexion—

547. As above, he must distinguish two cases:—

1st, WHEN HE SEES THE COLOURS MODIFIED BY JUXTAPOSITION ONLY, _when the tint may be lowered without leaving its scale_:—

1. By a black drapery, which lowers it by contrast of tone. 2. By a drapery of the same scale as that of the tint, but of a much higher tone.

Such, perhaps, as a red drapery upon a rosy complexion; or, an orange drapery upon an orange-tinted complexion; or, the effect of a dark green drapery on a complexion of a green tint.

2nd, _The tint may be lowered by making it leave its scale_.

1. By a green drapery of very dark tone, upon an orange complexion. 2. By a blue drapery of a dark tone, upon a rosy complexion. 3. By a very dark yellow drapery, upon a very pale orange complexion.

APPLICATIONS TO HORTICULTURE.

SECTION I.

548. The applications I propose to make are of two kinds: the one relating particularly to the arrangement of plants in gardens, according to the colour of the flowers; the other, to the method of distributing and planting ligneous plants in masses, which I suppose to have been previously planned. Doubtless, I need not have discussed the latter subject, but I have been led to it so naturally, and the rules which guided me are so positive and simple, that I have no doubt of their proving profitable to those of my readers who follow them in laying out plantations, &c.

The artist who conducts these operations is called a Gardener, or Landscape Gardener.

ON THE ART OF ARRANGING ORNAMENTAL PLANTS IN GARDENS SO AS TO DERIVE THE GREATEST POSSIBLE ADVANTAGE FROM THE COLOURS OF THEIR FLOWERS.

549. Among the pleasures afforded us by the cultivation of choice plants, there are few so intense as the sight of a collection of flowers, varied in colour, form, size, and position. It is probably because we admire the plants individually, and become attached to them on account of the pains they cost us, that we have hitherto so generally neglected to dispose them in such a manner as to produce the best possible effect when their flowers are seen collectively.

Thus, no defect is more common than that of the _proportion_ in which flowers of similar colours are distributed in a garden. Sometimes the eye is struck by blue or white, sometimes it is dazzled by yellow. Add to this defect of proportion, the ill effect produced by placing together many species of flowers, which, although of the same colour, are not of the same tint: for instance, in spring we see the leopard's bane (_doronica_), of a brilliant golden yellow, side by side with the narcissus, which is of a pale greenish yellow; in autumn, the Indian pink beside the African marigold, dahlias of various reds grouped together, &c.

Such arrangements as these cause the eye, accustomed to appreciate the effects of contrast of colours, to feel sensations quite as disagreeable as those experienced by the musician whose ear is struck with discords.

550. Previously to my observations on simultaneous contrast, and the demonstration of the law which governs it, it was impossible to prescribe rules which, by instructing horticulturists to place, with certainty of success, flowers in proximity whose colours reciprocally enhance each other, enabled them to avoid either the monotony resulting from the grouping of flowers of the same colour, or the disagreeable effect of a collection of flowers whose hues are mutually injurious.

ASSORTMENTS OF FLOWERS,

Where the Plants are apart.

551. The associations of flowers which relate to the harmonies of contrast of colour, are first, those with colours mutually complementary to each other; such as blue with orange, or yellow with violet. Rose or red flowers contrast with their own leaves.

552. White flowers accord more or less favourably with blue and orange flowers, already allied together; and perfectly with rose or red flowers, but not so well with yellow or violet flowers, already allied. White associates much less favourably when the latter is brighter or greener.

White flowers are the only ones that possess the advantage of heightening light tones of any colour, and of separating those whose colours are mutually injurious.

553. Yellow flowers, especially those which incline to orange, accord very well with blue ones.

Flowers of a yellow, more green than orange, have a very good effect with flowers of a red inclining to blue, rather than to orange.

Deep red flowers accord well with deep-blue flowers.

Orange flowers are not misplaced near violet flowers.

ASSORTMENTS RELATING TO THE HARMONIES OF CONTRAST OF HUES.

554. It is so difficult to make associations of hues which will have a satisfactory effect, that I prescribe _in general_ the mutual association of flowers whose colours belong to neighbouring scales.

We must then separate

Pink flowers from those that are either Scarlet or Crimson. Orange ” ” Orange-yellow, Yellow ” ” Greenish-yellow,

I shall even go further in advising the separation of— Red flowers from Orange, Blue or Pink from Violet.

Where the Plants are indiscriminately mixed.

555. Flowers which only present contrasts of hues and which spring from seeds sown thickly in borders, or in beds, will not have the same objection as when the roots are planted at a distance from each other.

556. Flowers, presenting a disagreeable contrast of hues, may still produce a good effect, when their assortment makes part of an arrangement of contrasts of colours, strongly opposed; in this case being no longer seen isolated, they become in a manner the element of a picture.

SECTION II.

ASSORTMENTS AS TO HARMONY OF ANALOGY.

557. I only reckon shrubs susceptible of this harmony; because only perennial plants afford to the horticulturist a guarantee that the flowers of one year will be identical with those of the preceding; consequently, if we plant woody shrubs in such manner as to secure a regular gradation of tones, the successive annual flowerings will be constantly according to that order. We may apply this kind of arrangement to standard roses.

558. But I do not advise any one to attempt submitting annuals to this arrangement, because of the uncertainty that exists in the tones of their colour.

Harmonies of Analogy of Hues.

559. If I have spoken against the associations of _contrast_ of hues (554), I am more inclined to speak against the associations of _analogy_ of hues, always remembering the restrictions I have stated above (Section 1). We must not forget that my intention is to describe assortments, whose good effects are certain. Now the more the colours contrast, conformably to our law, the more latitude there will be, although the colours of individual flowers associated vary in tone and in hue.

560. An objection might be addressed to me _that the green of the leaves, which serves as a ground to the flowers, destroys the effect of their contrast_. But it is not so; and to be convinced of it, it is sufficient to fix upon a screen of green silk, two kinds of flowers in conformity with the arrangement of the coloured bands (_pl. 1. fig. 7_), and to look at them from a distance of about ten paces; for when the eye is fixed on two well-defined objects simultaneously, surrounding objects, especially distant ones, produce but feeble impressions.

ON THE ART OF ASSORTING LIGNEOUS PLANTS IN GARDENS, SO AS TO DERIVE THE BEST POSSIBLE ADVANTAGE FROM THE COLOUR OF THEIR FOLIAGE.

561. If we consider trees and shrubs no longer under the relation of the colour of their flowers, but with regard to the manner in which we may employ their foliage in the decoration of gardens, we shall perceive that there is only a very small number of contrasts of scale and hue which we can realize while vegetation is active; yet in autumn, when plants, losing their leaves before falling, assume various colours, as red, rose, scarlet, orange, and yellow, these, by their brilliancy, recall the season of flowers.

Most trees and shrubs present, in the summer season, only the green of their foliage; and, although this green varies in tone and hue, the differences are always trifling.

562. _Harmonies of Contrast._—The most decided contrast of colour that we can establish between the leaves of ligneous plants, is that of green, with foliage nearest to red. But even the _purple beech_ is more of a red-brown than a dark _red_, properly so called, for the colour of leaves results from a mixture of red and green, which, according to the principle of mixing colours must produce black, if they are in suitable proportion, or a brown tone of the green or red scale, according as one or the other colour predominates. The contrast of hue is established by the assortment of a bluish-green and a yellowish green of tones unequally high, by the contrast of a bluish-green brown with a yellowish light green, &c.

563. _Harmonies of Analogy._—Nearly all the masses of various trees in our landscape gardens present certain harmonies of hues mostly resulting from associations established according to considerations foreign to those of the assortment of foliage—an evident result, remembering (561) that the colours of the leaves of the greater part of plants are of green belonging to scales more or less allied, and of tones but little distant from each other.

(_a_) Harmonies of analogy of hues formed of allied tones belonging to neighbouring scales, are those which it is least difficult to obtain.

(_b_) Arrangements of foliage presenting a series of equidistant tones of the same scale of green.

ON THE DISTRIBUTION AND PLANTING OF TREES, ETC., IN MASSES.

564. The principal object of the two following chapters is to supply a deficiency in works on gardening as to the manner of distributing and planting trees in masses, &c., the outlines of which have been previously sketched conformably with precise rules. For authors say nothing on this subject, and the embarrassment of a landowner who wishes to plant an estate already planned out, is further increased by this circumstance, that, in the majority of cases, the author of the plan of the projected garden, after having defined the lines of the plantations, indicated the places where isolated trees must be placed, designated the kinds of trees which should constitute groups, and others which must enter into the formation of masses with trees and shrubs (which he does not generally indicate), leaves the care of planting and other details to ordinary gardeners.

Yet the distribution of trees and shrubs, however easy it may appear, in a piece of ground otherwise perfectly planned, contributes more than is generally supposed to the pleasure of a landscape garden, and presents also more difficulties than to allow of its being effected in a satisfactory manner, when it is abandoned, as generally happens, to chance. In fact, if, at the end of a few years, we observe the greater part of masses planted as they frequently are, we shall be struck with defects which were not at first perceptible, because we were then under the influence of the pleasure we always experience at witnessing the development of plants which have been confided to a carefully prepared soil; and besides, there are some defects which are only perceptible after a certain time, such, for example, as that resulting—

1. _From the plants being placed too near together._

2. _From placing, in the front row, clumps which rise too high, or which lose their lower branches._ Such are the elder tree, and sumach.

565. It was after many years of lost enjoyments, through having planted without fixed rule, masses otherwise well designed in their contours, that I was led by my own experience to seek the means of avoiding similar errors in future. The rules I now give are not the result of reflection merely; they have been practised many years, and I am much deceived if those who observe them will not derive great facilities in their application, and experience from them a lively satisfaction.

566. I will now define several expressions employed to designate the different associations of plants which may form part of a landscape garden.

An assemblage of trees and shrubs, occupying a large space, is termed a _forest_. But in a landscape garden a similar assemblage, or that which has been arranged to present the appearance of a vast space, is called a _wood_, if it is composed of trees and underwood; and a _park_, if it consists of trees only.

[Illustration: ARRANGEMENT OF PLANTS IN LANDSCAPE GARDENING.

PLATE XVIII.]

A collection of trees, shrubs, bushes, and underwood, is called a _grove_; when it consists only of trees, it is termed _a group of trees_.

There are _thickets_ of shrubs, bushes, underwood, and of flowering herbaceous plants.

There are _thickets_ formed of a single species of plants, and thickets formed of several species. The first are called _homogeneous_, and the second _heterogeneous_, or _varied_.

There are _isolated masses_, and _masses subordinated together_.

A small mass of flowers or shrubs, isolated, and of a circular or elliptical form, is called a _bed_.

CHAPTER I.

Of Lines of Plants.

567. I call a _line of plants_, plants placed at equal distances from each other, in straight or curved lines: these plants may be trees, shrubs, bushes, underwood, or flowering herbaceous plants.

568. A _line of plants_ of sufficient extent, and of which the plants are close enough to conceal from view objects placed behind them, is called a _screen_.

All masses planted according to my method are composed of lines of plants parallel to each other; in other words, there is between two similar lines an equal distance throughout. But the distance between the first and the second may differ from the distance between the second and the third, and so of the others. The result would be the same if the lines were closed curves, as, for instance, circles or ovals. The lines of plants are the elements of the masses.

ARTICLE I.

Of the Lines of Plants called Screens.

569. When we desire to conceal any object of considerable extent, we have recourse to a _screen of plants_. Whenever the extent of the land will not permit of the planting of several lines, constituting a mass, evergreens, such as thujas, almond-laurels, &c., are those to be preferred, succeeded by the hornbeam, lilac, privet, &c.

The most homogeneous screens, that is to say, those which are formed of a single species of plant, are preferable to all others for the object they are intended to fulfil; and to avoid the monotony of a single species, we must have recourse to one which offers varieties. For example, a screen composed of violet and white lilacs, will possess at the same time the advantage of homogeneity for concealing what is behind it, and the advantage of variety of foliage; the leaves of the violet-lilac being of a less yellow-green than those of the white lilac. We may alternate one or more plants of violet-lilac with one plant of white lilac.

Of Lines of Plants considered as Elements of Masses.

570. 1st. If the plants in the same line are not of the same species, it is essential that they do not differ too much from each other in respect to height.

2nd. Where a line happens to be entirely seen, the same species must be placed alternately.

3rd. We must avoid placing the same species in two neighbouring lines, when we would employ varied masses which are composed of several lines only.

RULE.—_When two lines of vegetation are planted to constitute a mass, in planting the first or exterior line, we must follow the rule indicated above_ (570), _then go on planting the second line, in the same manner as the first, except that the stakes indicating the centre of vegetation must be placed chequer-wise relatively to the centre of vegetation of the first line._

I will cite an example of a plantation of two lines intended to conceal a wall.

1st _Line_. 1. Almond-laurel. 2. Violet-lilac. 3. Laburnum. 4. Violet-lilac. 1_a_. Almond-laurel, &c.

2nd _Line_. 1. Clump of _prunus mahaleb_. 2. _Idem_, &c.

The distance between the clumps of the first line is four or five feet.

We may plant the first line in _screen_, and the second with trees larger than in the first; we may also plant the second line with roots of _prunus mahaleb_, comprehending between two roots three or five clumps of the same species.

Of Homogeneous Masses.

571. The _homogeneous mass_ includes only a single species of plant, because the intention of the gardener in forming it, is to produce an effect of _individuality_.

In the large French garden, designed by Le Notre, where the trees combine so effectually with the elements established by the architect, to prolong, so to speak, a similar work, the symmetrical plantations are identical, and generally composed of trees of a single species.

572. Although homogeneous masses of trees have a good effect in a large composition, it is not so with those which are composed of a single species, or of a single variety of flower. They almost always present a monotonous aspect, especially if the latter have a definite extent; and if the species of plant of which they are composed is in flower only a part of the year, the defect of monotony will be greatly increased. Homogeneous masses of shrubs or of flowers are only suitable when they are in leaf or in flower during a great portion of the year; as their extent is small, and they serve simply as a bond of union between different parts more or less distant from each other.

Of Heterogeneous or Varied Masses.

573. I shall distinguish two cases—one where it is a _heterogeneous_ or _varied_ mass, isolated, intended to serve as an individual composed of distinct parts; and the other where it consists of many varied masses, allied together, and separated by paths, at least in some parts.

Isolated Masses.

If each line consists of only a single species, we must arrange the lines according to their size. For example—1. Lilacs. 2. Laburnum. 3. Judas trees.

574. _Heterogeneous or varied masses_ placed together so as to form a whole, are generally separated from each other by glades, or unplanted intervals, but cultivated or sown in grass, or by paths. To make what follows thoroughly understood, I must point out the essential difference that exists between landscape gardening and French (geometrical) gardening.

575. French gardening is regular and symmetrical, the paths are straight, and the eye is only impressed by objects slightly varied; for when there are squares or straight borders, symmetry necessarily requires that the objects on one side be repeated on the other. The result is, that when the spectator has visited the principal points of this composition, which are never very numerous, he has seen everything it has to offer to his curiosity.

576. I will not say, with some writers, that landscape gardening is conceived with an entirely different aim. The spectator who surveys a landscape garden, should be excited, so to speak, at every step, by the sight of various objects. The different points of view must be as numerous as possible, the paths must always, therefore, be traced, so that from no point can their whole extent be discovered. The plantations must be disposed so as to conceal the walls, fences, or other disagreeable ill-placed objects. They must allow the eye the greatest possible scope, at all the points the gardener wishes to be displayed; and the views must vary with the different points successively observed.

577. To achieve this, it is evident that there must be no straight paths, but only curved ones. When paths pass between masses, the intervals between these masses must also permit to be seen groups of objects, which must form planes, skilfully prolonging the perspective, as far as possible. The masses, though varied, must nevertheless be allied together, so that neighbouring masses may harmonize as dependent parts of the same whole.

ARTICLE II.

578. _Harmony between masses distant from each other_, in which harmonies may be established by the same general means as they are between neighbouring masses. The foliage in the masses being much more abundant than the flowers, the shades of their greens will not differ so much from each other as the colours of their flowers; consequently, the distant masses, however varied in their foliage, are always in harmony of form and colour, if they have been planted according to our rules; and if they are composed solely of ligneous plants, which lose their leaves in winter, or solely of evergreens, which do not lose them; but in the opposite case, that is to say, when the masses are formed, the one of deciduous trees, and the other of evergreens, some remarks must be made relative to the conditions of harmony, which are the more necessary, as even the most studied landscape gardens generally err in this respect; for a clump or a mass of evergreens is almost always out of keeping in a large space where masses of deciduous trees are found. To remedy this defect we must multiply the groups or masses of evergreens, so as to establish between all of them this same correlation which is required by deciduous trees; but it is not necessary that the trees should occupy a space equal to that occupied by ordinary trees; it is sufficient if their forms recur at suitable intervals. In a word, for evergreens to produce a good effect, they must compose a whole, which unites or intercalates with the general effect of the masses of deciduous trees.

We may oppose allspice trees to pines, cedars to larches; different groups, composed of three or four trees only, suffice to harmonize a large space of ground occupied with two or three groups composed of half a hundred similar trees.

579. _There are certain cases in which the want of either perspective or harmony requires, in a large mass, a line of trees which is neither concentric with its circumference, nor identical with the central line, if there be one; such, for example, as the line P. R., which is found in the masses 1 and 2_ (Pl. 18); _for if the planting of this line be correct, and according to the preceding principles, the trunks, which define it, beyond the concentric plantings, must be in the points of intersection of the line P. R., with the concentric lines, and the central line, if there be one; and the trunks must be as much as possible at equal distances from each other._

Such a plan, always easy to make, will enable a landowner, when once his masses are planned, their concentric lines traced, and the species to be planted determined upon, to order from the nurseryman the exact number of each species he requires.

580. _After tracing the lines of plantations, and putting in the stakes to mark out the centre of the holes to be dug, we must draw upon grey paper lines representing those of the masses we intend to plant, taking as many equidistant points as there are stakes in the corresponding lines of plantation; we then fasten on these points wafers, or little circles of paper, of the colour of the flowers or the foliage of the plants, according to the desired effect._

By this means we can judge of the harmony of the colours of flowers with the different hues of green composing the mass, and thus rectify any defect in the plan before we begin to plant.

The principles on which the preceding rules are founded are those of height, form, variety, facility of development, and distinctness of view. Harmonious arrangement, with reference to these points, not being so exclusively the object of this work as the subject of colour, must be passed with this indication.

Contrast of Colours.

581. This principle, regarded generally, is included in the preceding, since a difference in colour will render plants distinct which have numerous analogies; but viewed specially, it produces among perfectly dissimilar plants, effects which can only be obtained from colour; and it is then that the principle of contrast is to be taken into consideration.

In the application of the law of contrast to the arrangement of flowers, we must never forget the difference between an assemblage forming a line of plants, and an assemblage of flowers belonging to plants of various heights, standing on different planes, so as to produce the effect of a picture. I have alluded to this before (551); for in a linear arrangement, for example, there is nothing more unpleasant than the blue flowers of the German iris, associated with the light violet of the lilac. But if we add to this association large tufts of _alyssum saxatile_, Persian iris, and red tulips, so that the golden yellow, white, and deep red, appear on one plane, and the deep blue and the light violets on a more distant plane, we shall obtain general effects of a most agreeable kind.

Repetition.

582. When a line of plants exhibits the repetition of the same species, and presents them regularly at the same intervals, an effect is produced which, although very agreeable, is but little appreciated—for it is very rarely met with in gardens. It is especially the repetition of a similar arrangement of colours that is agreeable, and which recommends the observance of this principle.

Repetition of the same arrangement of plants of various kinds, and of course distinct to view, contributes greatly to prolong the extent either of an alley or of a mass; a similar general effect repeated a certain number of times becomes a standard, by means of which the eye judges the space to be greater than if it were bordered with individuals of the same species or variety equal in number to the former. This effect is carried to the utmost extent when the arrangement is composed of a certain number of tufts—five, for instance—placed between two trees, which rise above them, but not too high.

Repetition and distinctness of view concur in producing an agreeable effect.

583. _Variety_, like every other principle, should never be carried too far, and it is a great mistake to suppose that plantations made without design, and which thus it might seem must be extremely diversified, produce in this respect more effect than those which have been arranged according to the principles of distinct view, contrast, and repetition.

Whenever objects must have a certain superficial extent, we gain nothing by multiplying varieties of them. Thus, the repetition of an arrangement of three colours, including white or black, will generally be more agreeable than that of an arrangement of five colours.

Diversity of colours, pushed to the extreme, can only be permitted in a continuous border, or a bed of different varieties of the same species of flowers, as a border of larkspur, china aster, or anemones; but, for flowering shrubs, we shall gain everything by not indefinitely multiplying their colour, in a view which the eye can embrace at once. And as with colours so with forms, which must not be too diversified in the same arrangement.

Symmetry.

584. We should deceive ourselves very much if we supposed the principle of symmetry to be excluded from landscape gardening. But, in order to perceive it or to put in practice, it is necessary to distinguish the _symmetry of similar parts_, and _the symmetry of parts merely corresponding_.

The former is that of two equal parts of one whole, as the two halves of a circle, of a square, of an equilateral or isosoceles triangle, &c.; while

Symmetry of parts merely corresponding, is that of two parts of the same whole, which, without being equal, have the same form, or nearly so; such are the two triangular parts of the Mass 3, Plate 18.

Or, that of two separate parts, more or less analogous in form, extent, or nature, which have a correspondence of position relatively to an intermediate object.

Or, that of two masses or groups of trees, or of a mass and a group of trees which are presented, the one to the left, the other to the right.

General Harmony.

585. In the general composition of a large landscape garden, it is not enough to have satisfied all these principles, if the different masses subordinated together, which we shall now regard as individuals, as well as the various constructions of wood or of stone, are not combined by some harmonious relation suitable for satisfying the principles of _general_ harmony. The isolated or subordinated masses near or distant from each other must be allied together by the same vegetable form or by analogous forms, or by the same arrangements of several species; or, lastly, by the same colours of flowers or of foliage. By the aid of similar means, we ally the house and other buildings to the different parts of the garden. When the neighbouring masses, especially those formed near buildings, are not sufficiently allied together, or the perspective of their concentric or median lines is not satisfactory, we have recourse to a different line of vegetation, which cuts the first and thus adds to the general harmony. Thus, as I have so strongly insisted, when we decide to plant evergreens in a landscape garden, they must be distributed throughout the composition.

SIXTH DIVISION.

INTERVENTION OF THE PRECEDING PRINCIPLES IN THE JUDGMENT OF COLOURED OBJECTS, RELATIVELY TO THEIR COLOURS, CONSIDERED INDIVIDUALLY, AND TO THE MANNER IN WHICH THEY ARE ASSOCIATED.

586. In this division my object is purely critical. The positive conclusions at which I have arrived upon certain assortments of colours, so as to derive the best result from them under given circumstances, become rules, adapted to guide those who would

judge a work of art in which such assortments occur. The generalizations established in the preceding chapters, with the object of aiding the numerous artists who use colours, now critically considered, will serve as the basis of a conscientious and sound judgment upon the merit of any work in which these generalizations are concerned. They will, I trust, possess the double advantage of all the rules involved in the nature of such things; they guide the workman who does not disdain them, and they direct the critic who judges the work of which these rules govern some element. We cannot then refuse to recognise the utility of such an examination, both for artists and for the public, to whom they are more particularly addressed, in the hope that a clear demonstration of what is laudable or censurable will form such a public taste as, by preventing a reliance on first impressions, will lead to a sound judgment; and that we may not henceforth strive to enlist public suffrages by falling into unsuitable singularity, or by wandering from the truth.

587. If there exists a subject worthy of being studied critically on account of the frequency and variety of the cases it presents, it is unquestionably this; for whether we contemplate the works of nature or of art, their varied colours form one of the finest spectacles man is permitted to enjoy. Hence the desire of reproducing the coloured images of objects which excite our admiration or interest, has produced the art of painting. The imitation of the painter's works has given birth to tapestry, and carpets, and mosaics; while the necessity for economically multiplying designs has led to ornamental printing. The love of colour has also induced man to paint his dwelling and to dye his garments and household decorations.

588. The sight of colours, so simple a thing for the greater part of mankind, is, according to some philosophers, a phenomenon entirely out of the domain of positive knowledge, inasmuch as they consider that it varies with the organization, and even the imagination, of individuals; consequently, they think that it cannot be inferred that, because one man sees an object in a certain way, another will see it in like manner under the same external circumstances. They believe that no generalization, deduced from observation, can direct the artist with certainty, either in the art of seeing his model or in faithfully reproducing a coloured image of it: they also think that no useful physiological generalization can arise from a profound study of the modifications his organs experience from the sight of the colours that bodies present to him.

I cannot admit that we ought to abstain from the study of a subject because it presents variable phenomena.

All those who are engaged in the study of the positive sciences, should inquire for some fact capable of illustrating the study of these phenomena.

589. I entered upon this study, not having spontaneously chosen it, but because it appeared to me indispensable before pretending to establish a sound judgment on the beauty of the dyer's colours. As soon as I felt the necessity for this study, in my capacity of Director of the Dyeing Department of the Royal Manufactories, my first care was to discover whether I saw colours as the generality of persons see them. I was soon perfectly convinced that I did, and not till then did I venture to make my researches the subjects of public lectures. These have been repeated before the students of the Polytechnic School. Certain questions addressed to my auditors to satisfy me that they saw the things I put before their eyes as I saw them myself, have, in the majority of cases, always proved them to be so, and yet my demonstrations were given in the reception-hall at the Gobelins,—a place ill adapted for the exhibition of the phenomena of contrast to a large audience. Certain observations by myself, tested by a great number of persons in my laboratory, and afterwards publicly exhibited, form the subject of this book; all who repeat my experiments will discover whether my opinion is well-founded, or whether an opinion is correct which pretends that the sight of colours is not capable of giving a general positive result. Because some individuals have organs of sight so imperfect that they cannot distinguish green from red, or blue from grey, &c., must we write our treatises on optics without mentioning either red, green, or blue, and cast away these colours from the palette? Assuredly human nature is too limited to allow of our making such a sacrifice of our common organization to the infirmity of an individual.

590. In order to comprehend clearly how experiment and observation, after having disentangled the causes which exercise a determinate influence upon the sight of colours, led me to adopt the opinion that these phenomena are perfectly defined by the law of contrast and the conclusions therefrom, doubtless it will suffice to consider how

1. Our former ignorance respecting the different states of the eye, which, in seeing colours, give rise to the phenomena of simultaneous, successive, and mixed contrasts.

And our former ignorance respecting the definite influence that the direct or diffused light of the sun exercises, according to its intensity, upon the colours of bodies, have led to the establishment of an opinion contrary to my own;—that is to say, the opinion that _the same colour appears so diversely to different persons, and even to the same person, that nothing general or precise can

be deduced from the sight of coloured objects, with regard to their respective colours_.

2. To consider how the following have passively contributed to belief in this opinion.

The limited number of ideas we have generally about the modifications of coloured bodies, by their mutual mixtures; or in other terms, upon the colours resulting from these mixtures.

The want of a precise language to convey the impressions we receive from colours.

591. It is indisputable that if we are ignorant of the regularity with which the eye passes successively through stages, the extremes and the mean of which are very different, in viewing the colours which put the organ into the condition of perceiving the phenomenon of one of the three contrasts (77) we shall be led to consider the sight of colours as a very variable phenomenon, _while the successive stages through which the organ passes being once distinguished, the variations of the phenomenon become perfectly definite_.

592. If we are ignorant of the law of simultaneous contrast, we shall suppose that the same colour varies in tint according to the colour with which it may be associated; and if we are ignorant that contrast affects the tone as well as the colour, we cannot explain how two similar colours (for instance, blue and yellow at the same depth of tone) will appear redder by juxtaposition; while, if the blue is very deep relatively to the yellow, it will appear black, rather than violet, and the yellow will appear more green than orange. Finally, if we are ignorant of the effect of the brightness which a complementary can give to a dull colour, we cannot explain the great difference there is between the effect that a red ground has upon imitative gilt ornaments, and the effect of the same ground upon metallic gilt ornaments (384).

593. Doubtless, also, if it be not known that in a complex object, the eye can only see clearly at the same moment a small number of parts and that the same part may appear to different eyes with different modifications, according as it is seen juxtaposed with one or another colour, as in the instance given (407).

594. We might know the regularity of the successive states of the eye during the sight of coloured objects, and the law of simultaneous contrast of colours, and yet, if we were ignorant of the influence of various degrees of intensity of light in varying the colour of bodies and in rendering the modifications of contrast more or less evident, we should be led to believe in an indefinite variation in the aspect of colours; but this variation is perfectly defined by the following remarks:—

If the direct light of the sun or diffused daylight illuminates a monochromous body unequally, the part most vividly lighted is modified as it would be if it received orange, and the modification appears the stronger the greater the difference of light on the parts (280): thus the more intense the light, the more it gilds the body it illumines; it is thus always easy to foresee the effects of it when we know the result of the mixture of orange with various colours.

595. The phenomena of simultaneous contrast being less evident in a very vivid light than in a weaker light (63), it follows that if we disregarded the difference in the effects, we should greatly deceive ourselves in our appreciation of the phenomena of contrast of similar colours. Simultaneous contrast, which tends to make the differently coloured parts appear as distinct as possible, is carried to a maximum, precisely when the light being feeble, the eye requires the greatest contrast of colour to perceive distinctly the various parts upon which it is fixed.

596. We may perceive the modifications presented by bodies when lighted, and yet we may experience much difficulty in accounting for them, for want of knowing how to represent exactly the modifications which the coloured materials experience, in their colour, according as they receive light or white, shade or black; or according as they are mixed together. It is partly to make these modifications clearly known that I have designed the _chromatic hemisphere_ (134, _et seq._). In describing it, I have attached less importance to its material realization than to the rational principle upon which it depends. On looking at the lines of this diagram independently of all colouring, we understand how any colour is reduced by white, deepened by black, and broken by black and white, and how, by mixture with a pure colour, it produces hues. I shall add subsequently some new considerations on the gradations of colour made with coloured materials.

My object would not have been attained had not the chromatic hemisphere given me the means of representing, by a simple nomenclature, the modifications which a colour undergoes by the addition of white and black, modifications which produce the _tones of its scale_; those which it receives from black yielding _broken scales_, and those resulting from the addition of a pure colour, produce scales which are _hues_ of the first colour.

597. Finally, to the definitions which I have given of the words _tone, scale, hue, broken colours_, I must add the distinction of the associations of colours into _harmonies of analogy_, and _harmonies of contrast_ (172).

I am convinced that all those who accept the small number of definitions I have given, will find much advantage from them in accounting for the effects of colours, and in expressing their views to others. By their aid it will be easy to notice relations which might have escaped observation, or which, in the absence of precise language, could not have been clearly communicated.

598. It would be ignoring a fact to attribute the opinion I have combated, exclusively to ignorance of what I have just recapitulated, or to believe, that in order to establish the contrary opinion, which I maintain, it is sufficient to dissipate this ignorance.

But I am satisfied with pointing out the error, without making the least pretension to overthrow it, otherwise than by stating what I believe to be the truth.

599. The study of the positive facts just reviewed, leads to a certainty in the view of colours which all may acquire who devote themselves to it. They will see how fruitful it is in applications, and that it is independent of every hypothesis, and that it would be impossible to obtain this result, if there did not commonly exist among men an average organization of the eye, which permits them to perceive in similar circumstances the same modifications, but with varied intensity of perception.

600. Having noticed the series of principles upon which my book is founded, I next consider these facts under the three following relations:—

1. The certainty they give in judging of the colour of an object.

2. The certainty they give to our judgment in the various arts which address the eye by coloured materials.

3. The union they establish between the principles common to many arts, which speak to the eye as it were various languages, in employing different materials.

4. The influence that the disposition of the spectator’s mind may have upon his judgment of a work of art.

SECTION I.

ON THE CONNEXION OF THE LAW OF SIMULTANEOUS CONTRAST OF COLOURS WITH THE JUDGMENT WE FORM UPON ALL COLOURED BODIES, UNDER THE RELATIONS OF THE RESPECTIVE BEAUTY OF PURITY OF THEIR COLOURS, AND OF THE EQUALITY OF THE DISTANCE OF THEIR TONES IF THESE BODIES BELONG TO THE SAME SCALE.

601. The most simple and general conclusion deduced from the law of contrast is certainly that which concerns the judgment we exercise, either by taste or profession, on a colour, whether presented by a coloured paper, a textile fabric, a glass, an enamel, a picture, &c. All those who have some experience in the matter consider one condition as essential to be fulfilled to avoid error, namely, that the colour concerning which we have to determine be compared with another colour analogous to it. _If we are ignorant of the law of contrast, the result of this comparison is not exact, whenever the objects compared are not identical._ I now proceed to demonstrate this by examples adapted to the application of the principle spoken of. Further, a more remote consequence of the law affords the means of knowing whether the tones of a scale of wool or silk are equidistant.

ON THE COMPARISON OF TWO SAMPLES OF THE SAME COLOUR.

602. When we have to do with two patterns of any kind, which are related to the same colour, if there is no identity between the tints, we must take into account the contrast which exaggerates the difference; thus if the one be greenish-blue, it will make the other appear less green, or more indigo, or even more violet, than it really is; and, reciprocally, the first will appear greener than when viewed alone; the same with the reds, if one is more orange than the other, the latter will appear more purple, and the former more orange, than they really are.

INFLUENCE OF A SURROUNDING COLOUR UPON ONE COLOUR WHEN COMPARED WITH ANOTHER.

603. Since the contrast of colours which are not analogous, tends to improve and purify them, it is evident that whenever we would exercise a correct judgment upon the beauty of colours, after comparing them with the colours of objects analogous to the first, we must take into account the kind of work, and the manner in which they are juxtaposed, if the objects compared are not the exact

representation of the same subject. For, other things being equal, the same colours not blended, and which are not sufficiently analogous to injure each other, will certainly appear more beautiful disposed in contiguous bands than if each were seen on a ground which consisted of it exclusively, and which consequently produced only a single impression of colour upon the eye. Colours forming palms like those of Oriental shawls or patterns, as of Turkey carpets, produce a much greater effect than if they were shaded or blended, as they generally are in paintings. Consequently, for example, in comparing a stripe of crimson in a Cashmere shawl of various stripes with the crimson of a French shawl, we must destroy the contrast of colours by placing around it a piece of grey or white paper, cut out so as to allow this stripe only to be seen, when the parts compared will be submitted to the same influence from the surrounding objects.

604. So, when we compare the colours of old tapestries, pictures, &c., with colours recently dyed or painted. Time acts very unequally, not only on the different kinds of colours of dyed stuffs, but also upon the tones of the same scale. Thus, the deep tones of certain scales,—those of violet, for example,—fade, while the deep blues of the indigo-blue scale, the deep tones of madder, kermes, cochineal, are permanent. Also, the light tones of the same scale fade during a time which has no sensible effect in altering its deep tones. Whence the colours which have most resisted the destructive action of time, being more isolated from each other, as well as deeper and less blended, appear to have more brilliancy. There are many pigments, as most of the lakes, which are in the same condition as compared with ultramarine, the oxides of iron, the blacks, &c.

On the Effect of Contrast upon the Browns and the Lights of most of the Scales of Wool and Silk employed in Tapestry and Carpets.

605. When we look at the whole effect of tones of most of the scales made use of in these manufactures, the phenomenon of contrast exaggerates the difference of colour observed between the extreme and the middle tones of the same scale. For instance, in the scale of indigo-blue, applied to silk, the lights are greenish, the browns are tinged violet, while the intermediate tones are blue; but the difference of green and violet at the two extremes is augmented by the effect of contrast. So in the scale of yellow, the light tones appear greener, and the browns redder, than they really are.

606. In speaking of a difference existing between the deep and the light tones of most of the scales of wool and silk, which is exaggerated by contrast, I will add some remarks relative to the gradations the dyer produces. This gradation is very seldom perfect, as the light tones are exactly represented to the eye by the colour taken at its normal tone, reduced by white. Thus, a compound which at the normal tone is pure yellow, or slightly tinged with orange, will, by reduction, produce light tones of a greenish-yellow. An orange-red compound upon silk or wool will yield light tones tinged violet-red. To obtain a correct gradation, we must in most cases add to the weak tones a new coloured material, adapted to neutralize or weaken the defect spoken of.

607. Many of the colouring matters used in painting produce the same result when reduced with white. I do not speak here of changes which may be the effect of chemical action; I allude only to those which result from an attenuation of the coloured material. For example, the normal tone of carmine is a much purer red than its light tones, which are evidently tinged with lilac. Ultramarine, so beautiful in itself, yields light tones which, with respect to the blue rays, appear to reflect more violet rays than the normal tone. In consequence of these facts, it is difficult to colour the chromatic diagram, because many trials must be made to obtain the modification of colour which yields the normal tone of a scale, by the addition of such coloured materials as will render the gradation correct.

MEANS AFFORDED BY CONTRAST FOR ASCERTAINING WHETHER THE TONES OF A SCALE OF COLOUR ARE EQUIDISTANT.

608. Contrast, which augments the difference existing between two tones of the same colour, affords the means of judging with greater certainty than could otherwise be done, whether the numerous tones of a scale are at the same distance from each other. Thus, if the tone 2, placed between 3 and 4, appears equal to the tone 1, it follows, if the tones are equidistant, that 3 placed between 4 and 5 will appear equal to 2; that 4 put between 5 and 6 will appear equal to 3, and so with the others. If the tones are too near together to yield this result, we must move them successively, not one degree, but two or three. This means of judging of the equality of distance that separates the tones of the same scale, is based upon the fact, that _it is easier to establish an equality than to estimate a difference between patterns of the same colour._

OF THE BINARY ASSOCIATIONS OF COLOURS, CRITICALLY CONSIDERED.

609. In order to sum up in few words the generalities which must serve as the bases of our judgment, not on one colour compared with another of the same sort, but on the associations of two colours, which any object whatever presents to our eyes, we must consider combinations both of complementary and non-complementary colours.

1st. _Combination of Complementary Colours._

This is the only association where the colours mutually improve, strengthen, and purify each other without leaving their respective scales.

This case is so advantageous to the associated colours, that the combination is also satisfactory when the colours are not absolutely complementary; also when they are made dull with grey. I therefore prescribe the complementary association when we have recourse to the harmonies of contrast in painting, in tapestry, in the arrangement of coloured glass windows, in the assortment of hangings with their borders, in that of stuffs for furniture and clothing; and, lastly, in the arrangement of flowers in our gardens.

2nd. _Combination of Non-complementary Colours._

The product of this combination is distinguished from the preceding in this,—the complementary of the juxtaposed colours, differing from the other colour to which it is added, there must necessarily be a modification of hue in the two colours, as well as a modification of tone, if they are not taken at the same height.

610. Juxtaposed non-complementary colours can _certainly_ give rise to three different results:—

1. They may improve each other. 2. The one may be improved, the other may lose some of its beauty. 3. They may injure each other.

The greater the difference between the colours, the more favourable will the juxtaposition be to their mutual contrast; consequently, the more analogy they will have, and the more chances there are that the juxtaposition may injure their beauty.

1. _Two non-complementary colours improve each other by juxtaposition._

611. Yellow and blue are so dissimilar, that their contrast is always sufficiently great for their juxtaposition to be favourable, although the juxtaposed colours belong to different scales of yellow and blue.

2. _One colour juxtaposed with another which is not its complementary, may be improved, while the latter may be injured._

A blue, which is improved by a yellow, being placed beside a violet (blue rather than red) may lose some of its beauty, by becoming greenish; while the orange it adds to the violet, neutralising its excess of blue, rather improves than injures it.

3. _Two non-complementary colours may injure each other._

A violet and a blue are reciprocally injurious, when the first greens the second, and the latter neutralizes sufficient of the blue in the violet to make it appear _faded_.

It might also happen that although the colours juxtaposed be modified, neither gaining nor losing in beauty, that the one may gain without the other losing; lastly, that the one may neither gain nor lose, while the other loses.

612. _In the association of two colours of equal tone, the depth of the tone may have some influence on the beauty of the association._

For example, a deep indigo-blue and an equally deep red, gain by juxtaposition; the first, by losing some violet, will become a pure blue, the second, in acquiring orange, will become brighter. If we take light tones of the same scales, it may happen that the blue will become too green to be good as a blue, and that the red, acquiring orange, will be too yellow to be a pure red.

613. _In the association of two coloured objects of tones very distant from each other, belonging to the same scale, or to scales more or less allied, the contrast of tone may have a favourable influence upon the beauty of the light tone_; because, in fact, if the latter is not a pure colour, its juxtaposition with the deep tone, upon the whole brightening it, will purify the colour from whatever grey it may have.

614. It is very necessary for the correction of our judgment of these principles on the binary associations of colours, not to lose sight of all that precedes, concerning colours that are “dead,” or without gloss, and that their combination be considered independently of

the form of the objects presenting them, for the twofold reason, that _the glossiness of the coloured surfaces, and the form of the bodies which these surfaces bound_, may modify the effect of two associated colours; consequently, the analysis I have made of the optical effects of colours would be incomplete without speaking of the possible influence of these causes.

Influence of Gloss taken into consideration in the Effect of Contrast of two Colours.

615. The optical product of the juxtaposition of contrasted flat colours is composed of two effects:—1. The effect which arises from each of the juxtaposed colours, by receiving the complementary of the colour contiguous to it, is thus strengthened or tinged agreeably, independently of any augmentation of gloss. 2. The effect arising from gloss in the two juxtaposed colours. Here it may be remarked that associations which I have not prescribed, such as red with violet, or blue with violet, have a fine effect in the plumage of certain birds and butterflies; for, in these natural associations, the effect arising from the addition of the complementaries to each, which would injure the _flat_ colours, is entirely insensible in surfaces which acquire _metallic brilliancy_ from their organic structure. Finally, I shall add, that it would be necessary, before raising the objection, to demonstrate that the same red, associated with green, the same violet associated with yellow, and the same blue associated with orange, equally glossy, would be less effective than in natural assortments.

Influence of Form taken into consideration in the Effect of Contrast of two Colours.

616. Elegance of form, the arrangement of the parts, their symmetry, the effects of light and shade, and the association of ideas which may connect this form with an agreeable recollection, will prevent the perception of the ill effect of two associated colours, even when not glossy. Thus, for example, in flowers, combinations, which would not produce a good effect upon two plain surfaces, are very beautiful. For example, the flower of the sweet pea, which has the combination of red and violet.

617. The critic must be directed by the considerations here summed up:—

1. The kind of association: the greater the difference between the colours, the more they beautify each other; and, the less difference there is, the more they will tend to injure one another. 2. The equality in depth of tone. 3. The difference of tone, the one being deep, the other light. 4. The glossiness of the surfaces which reflect the colours to the eye. 5. The form of the coloured body.

OF THE COMPLEX ASSOCIATIONS OF COLOURS, REVIEWED CRITICALLY.

618. It is evident that the rules prescribed for judging of a colour, and the associations of two colours, in an absolute manner, must serve for judging as to the colours of an association, however complex it may be. We shall consider the masses of colours which are upon the same plane, the extent which each occupies, and the harmony which unites them. On submitting to a similar examination the colours on the other planes, we can then look at the colours of the latter. The critic who is well satisfied with seeing clearly at the same time, only a very small number of the objects that a picture presents to him and who is also accustomed to examine a coloured composition in this manner, is in the position of a person who reads in succession writing on the same side of a sheet of paper; one series of lines crossing the first at right angles, and the third composed of lines running diagonally across the paper. The critic must review the _ensemble_ of the picture as to its colours, and then, being attentive to their particular and general associations, he will be in a condition to enter into the thought of the painter, and to see whether he has employed the most suitable harmonies to express it. Although it is easier to form with opposed colours than with neighbouring colours binary assortments favourable to the associated colours, yet, when a great number of pure and brilliant colours are employed, it is more difficult to harmonize them than if we produced the effect with a small number of colours, which would involve only the harmony of analogy, or that of scale, or of hue.

619. Although harmony of contrast most favourably causes two colours to impart value to each other, yet, when we desire to derive the greatest advantage from a union of numerous brilliant colours in any work—a picture, for instance,—this diversity presents some difficulties in the general harmony, which a smaller number of colours, and especially of brilliant colours, would not present. It is, therefore, evident that, if we compare two effective pictures, well adapted to be judged under the relation of colour (other things being equal), the one which presents more harmony of contrast of colour will have the greater merit, on account of the difficulty overcome in the employment of the colours; but it must not be inferred that the painter of the other picture is not a colourist; for the art of colouring is composed of several elements, and the talent of opposing pure colours to each other, is only one of these elements.

620. Let us now consider the relations existing between the subjects of painting and the harmonies they admit of. We know that the more pictures address the eye by numerous contrasts, the more difficulty the spectator experiences in fixing his attention; especially if the colours are pure, varied, and skilfully distributed upon canvas. It results, therefore, from this, that these colours, being much more vivid than the flesh tints, the painter who wishes that his idea should be found in the expression of his figures, and who, deeming this part of his art superior to the rest, is convinced that the eyes of most people ignorant of the art of seeing, being carried away by their first impressions, are incapable of returning from these to receive others;—the painter, I say, who knows all this, and is conscious of his power, will be restrained in the use of harmonies of contrast, and prodigal of the harmonies of analogy. But he will not derive advantage from these harmonies, especially in a subject covering a vast space filled with human figures, as the “Last Judgment” of M. Angelo, unless he avoids confusion by correct drawing, by a distribution of the figures in groups, skilfully distributed over the canvas, so that they may cover it almost equally, yet without cold symmetry. The eye of the spectator must embrace all these groups easily, and seize the respective positions; while in looking into one of them he must discover a variety which will invite his attention to other groups.

621. The painter who fails to gain the effects of the physiognomies, &c., in having recourse to the harmonies of analogy, will not have the same advantage in fixing general attention, as the painter who employs the harmonies of contrast.

The harmonies of contrast of colour are especially applicable to scenes (illumined by a too vivid light), representing fêtes, ceremonies, &c., which may be sober without being mournful; they are also applicable to large subjects, comprising groups of men animated with various passions.

Hence, the critic must never compare the colouring of two large compositions without taking into account the difference which may exist in the suitableness of each subject with one kind of harmony rather than with the other.

Painting in Flat Tints.

622. To apply painting in flat tints to historical, portrait, and landscape painting—in a word, to the imitation of any object of which we can produce a faithful representation, would be going back to the infancy of art; but to abandon it to practise exclusively the system of painting where all the modifications of light are reproduced according to the rules of chiaro-’scuro, would be an error which can be demonstrated beyond question.

1. That, in every instance in which a picture must be placed at such a distance from the spectator that the details of chiaro-’scuro will not be visible, we must have recourse to flat tints,—not neglecting, however, to use masses of light and shade adapted to give relief, if it is considered suitable.

2. That, in every case where the picture is necessary to the decoration of an object, flat tints are preferable to chiaro-’scuro, because the use of the object almost always prevents the picture which ornaments it from being clearly seen under all circumstances. Thus painting in flat tints is preferable to the other—

For ornamenting boxes, tables, screens, which, from the various positions their use requires, only allow to be seen a part of the pictures which decorate them; or, if the paintings are entirely visible, as those of a screen, they will be presented relatively to the daylight in a manner quite different from each other, on account of these various positions of their parts;

For decorating curved surfaces, as those of vases, the surfaces of which are never plain.

3. That the qualities peculiar to painting in flat tints are:—

Purity of outline; Regularity and elegance of forms; Beautiful colours properly assorted.

Whenever suitable, the most vivid and the most contrasting colours may be advantageously employed.

Simplicity in the whole, so as to render clear and distinct view easy.

OF THE ARTS WHICH ADDRESS THE EYE BY EMPLOYING COLOURED MATERIALS OF A DEFINITE SIZE, CONSIDERED RELATIVELY TO THE PHYSICAL CONDITION OF THESE MATERIALS, AND TO THE PECULIARITY OF THE ART IN WHICH THEY ARE EMPLOYED.

623. If we examine paintings with sufficiently powerful magnifiers, we shall see that the coloured material, far from being continuous in all its parts, is in separate particles, and consequently, if the naked eye does not perceive them separately, it is because they are

too small. In fact, the coloured threads (elements of tapestries and carpets), and rigid coloured prisms (elements of mosaics), which are visible to the naked eye, may be reduced to such a state of division, and so mixed and combined, that at the distance from which we view them united they appear as a uniform coloured surface—as if painted; whence the possibility of making, with these elements, works which correspond to those painted in chiaro-'scuro; but it will be easier to execute such as correspond with flat tints.

TAPESTRIES, CARPETS, MOSAICS, AND COLOURED GLASS WINDOWS, CORRESPONDING TO PAINTINGS IN CHIARO-'SCURO.

Tapestries with Human Figures.

624. Tapestries with human figures derive their origin from the taste of mankind for painting. They had adorned churches, palaces, and castles, before they appeared in simple dwellings.

From the filamentous condition of the elements constituting them, their size, the direction the weaver gives them in twisting the weft upon each thread of the warp, results a coloured image presenting two systems of lines cutting each other at right angles. From this structure it results, that a tapestry will not produce the effect of a painting (the surface of which is entirely uniform), if the spectator does not view it from a point sufficiently distant; so that, these lines ceasing to be visible, the delineation which separates each part of the design from the contiguous parts, will appear like the delineations of a painting, as much so as the indentations of the outlines which are oblique to the weft will permit. Hence _the objects represented by it must be large, of various colours, forming harmonies of contrast rather than harmonies of analogy_.

625. Every model which does not fulfil the previous conditions is bad, and as, in pictures which have not been painted with the intention of being reproduced in tapestry, it is difficult to meet with the union of pure outline with harmonies of colours sufficiently numerous and contrasted, it follows that what would be very advantageous to the art, is the execution of pictures intended to serve exclusively as models, painted broadly, so as to resemble, in some degree, painting in flat tints.

The weaver not having, at least at present, models painted on this system, has to make, not only, as we say, _a translation_, but also _a free and not a literal translation_, of the model; and it is this, in my opinion, which distinguishes the artist-weaver from the mere _workman_. Far from contending, then, with painting, the weaver, on the contrary, must study the circumstances in which he should yield in the struggle, so that he may avoid the difficulties with the means at his disposal; and when, especially, he must deviate from his model.

Tapestries for Furniture.

626. The preceding consideration respecting the size of objects that figured tapestries should reproduce, is not applicable to tapestry for furniture, seeing that the threads of the warp produce lines which, far from being disagreeable, are often imitated by the paperstainer.

627. These fabrics being intended for chairs, couches, curtains, screens, &c., the painter charged with composing designs for this class of works, must never forget that tapestries may occupy dark places, where they are imperfectly and often indistinctly seen; consequently he must select simple and elegant forms, in harmony of colour with the tapestry, &c., in the apartment. These models, even more than those for tapestries with human figures, must assimilate with painting in flat tints.

From among the facts I could quote to support this opinion, I shall select the following. There was a deep rose-red curtain, the centre representing a large bouquet of flowers of various colours, framed, as it were, in a garland of white roses. The artist had painted the model under the idea of executing this garland with silver thread; but this metal being objectionable, on account of its tarnishing by various exhalations, preference was given to white and grey silk, imitating the tones yielded by a silver object in relief. An experiment showed that it could not be attained by these means, because the contrast of the ground made all the half-tints appear _green-grey_, and these in their turn made the lights appear rusty-pink, in consequence of the greenish colour of their contrast. This annoyance being communicated to me, I advised M. Deyrolle, in reproducing the model, to make use of only three light tones of the rose scale in silk, and a white linen thread. By this means I expected that the complementary of the ground, neutralizing the rose, would produce a greyish half-tint, well adapted to set off the white. The result was such as I had foreseen. A second copy, made with a mixture of the light tones of the pure rose scale, slightly broken, gave an image less white, less _silvery_ than the preceding; or, in other terms, appearing a little greenish when compared with the first, and more harmonious. It resembled

the effect obtained with rose-red under lace or tulle, which permits little of the ground to be seen. This example indicates the means of executing white designs upon any kind of ground.

Savonnerie Carpets.

628. Carpets are larger than the tapestries for hangings; on the other hand, being liable from their position to be soiled by the feet, and to receive furniture on some part, they are in a less favourable condition than tapestries for being distinctly seen. This, then, is one reason why we should choose models, of design and colour adapted to the circumstances necessitated by custom, and in harmony with what is around.

Mosaics.

629. Mosaics being composed of minute prisms, and of materials susceptible of polish, we can rigorously copy very small objects, and, consequently, approach much nearer to painting in chiaro-'scuro than by employing threads. But to arrive at this result, without being unfaithful to the peculiarity of the art, the materials must be sufficiently solid, and joined together so intimately as to resist the agencies which would destroy a painting; for if this end be not attained, we cannot see the use of copying a picture in mosaic. So that to justify the production of such works, we must make sure that, in the situations in which they are placed, they will resist the agents which would destroy the works of the painter.

Windows of Coloured Glass.

630. A work executed in small prisms of transparent coloured glass, in imitation of painting in chiaro-'scuro, would be a true transparent mosaic. I do not know that such an imitation has ever been executed.

All the coloured glass windows which I have spoken of as decorations of Gothic churches, are composed exclusively of small pieces of glass of uniform colour, united by strips of lead or of iron; or altogether of these small pieces of glass, and of glass upon which we have applied with a pencil materials which afterwards have been vitrified: we can only entertain the question of the latter in this article.

We may propose two different objects in the production of these windows: either the coloured pieces are altogether secondary in the work, that is to say, occupying a much smaller extent of surface than the others, they do not attain to the perfection of painting,—such is the case with the greater part of the windows of large Gothic churches,—or else these pieces are the principal parts, which, predominating over the others, we attach great importance to the design and to the gradation of tints; such are several windows executed at the Royal Manufactory at Sèvres. The more such works resemble the preceding windows by the effect of their variety, brilliancy, and apposition of colours, the more they attain the object they must essentially fulfil.

Tapestries, Carpets, Mosaics, and Coloured Glass Windows, corresponding to Painting in Flat Tints.—Tapestries with Human Figures.

631. Although I have advised for tapestry models executed on the system of painting in chiaro-'scuro to resemble painting in flat tints, yet I shall not recommend taking the models entirely according to this latter system.

Tapestry for Furniture.

It is quite otherwise with patterns of tapestry for furniture. I believe that we can make some very beautiful works by copying patterns in flat tints; and that, in the decoration of large apartments, we may obtain an excellent effect from this kind of tapestry. I believe, also, that it would be more suitable for forming part of a general system of decoration, than the kind of tapestry of which I have spoken in the preceding article. Moreover, it is more favourable than the latter to the splendour of the colours.

The preceding observations are entirely applicable to the production of carpets.

Mosaics.

632. Mosaics being composed of more rigid and coherent coloured materials than are employed in the arts which combine coloured materials, I believe that it will be requisite, in judging works of this sort, to consider the power of the materials to resist the effects of friction, water, and atmospheric agents as essential qualities; the colour will follow.

Windows of Coloured Glass.

633. Considering coloured glass windows under the threefold relation of transmitting light into large Gothic churches, of their accordance with the decoration of objects consecrated to the rites of the Church, of transmitting a coloured light entirely in unison with the religious sentiments, I prescribe a uniform colour for rose windows and straight windows with circular or pointed tops, the smallest number of colours in the glass, glass of uniform colour predominating over the other to produce the best possible effects of colour.

OF THE DISPOSITION OF THE MIND OF THE SPECTATOR IN RESPECT TO THE JUDGMENT HE FORMS OF AN OBJECT OF ART WHICH ATTRACTS HIS EYE.

634. It is not enough to have indicated the rules to be followed and the principles to be observed in the production of effects, and the judgment of them in relation to art; we must also speak of the disposition of the spectator for receiving, more or less intensely, the impression of those effects. To take no notice of this disposition would be to display ignorance of human nature, and of the utility of the examination, which should be impartially pursued also by the critic, who may exaggerate blame as well as praise.

Without examining the influence that the passions exercise in opinions formed on works of art, I will say a few words upon a predisposition which may be remarked in a portion of the public, at least at certain epochs, and which has its source in man's vanity; then I will point out the part which the association of ideas performs in our adoption of opinions.

635. When a body of painters, called a _school_, has produced some _chefs-d'œuvre_, it frequently happens that a great number of mediocre works, executed under the pretence of continuing them, far from being favourable, are, with a portion of the public, injurious to them, on account of the monotony resulting from an imitation, more or less servile, of their form, colour, and even of their subjects. The public, under these circumstances, are ready to applaud any innovation that will excite emotions which it has not for some time found in contemporary painting, and it is then that amongst the public, voices are raised against great works, which have nothing in common with the tame imitations of them produced by mediocrity. Indeed, there comes an epoch when innovation, losing the only advantage it possessed of presenting to the eye images differing from those which it had been a long time accustomed to see, the public returns to the _chefs-d'œuvre_, and forgets all the feeble works composed in imitation of them by feeble pupils; and we will add that, if works _professing to be of the new school_, and endowed with undeniable merit, should exist, they would, in the estimation of connoisseurs, take the places they ought to occupy; whilst those which had arrested attention by innovation only, would disappear for ever.

636. Finally, to notice the effect which associations of ideas have on our opinions. For example, he who arrives at Versailles, full of admiration for the age of Louis XIV., repeoples the gardens with all the great men that have frequented them, and his thoughts recurring to the _fêtes_ given by an elegant and polished court, the admiration of Europe, he will judge the work of Lenôtre more favourably than he who, without being hostile to the _grand siècle_, will see nothing but a garden subordinate to a palace. And the Christian who associates in his mind the architectural form, the brilliancy of the coloured glass, and the religious ceremonies of the Gothic Church, all which he has venerated from his childhood, will be in a disposition to prefer the cathedral of Cologne to that of St. Peter's at Rome; while the latter would be associated with the profoundest veneration in the mind of a Christian of Rome.

ON THE COLOURS OF MILITARY UNIFORMS.

The following section, in which are described the advantages of contrast with regard to the heightening and purifying of the colour of cloths for dress, properly belongs to the chapters on clothing, pp. 165, &c. But, as in the present day, the colours of men's ordinary dress are not usually very various or strongly contrasted, this portion of the work has a more special application to military uniforms; the choice of colours being regulated by the principles laid down and exemplified throughout the work.

And, independently of economical considerations, the selection and arrangement of colours for military uniforms demand investigation as to the prominence or obscurity resulting from their combination, as well as to their æsthetical effect.

Of Uniforms composed of Complementary Colours.

By the law of contrast, red and green of similar tone in the same uniform, will heighten each other. Let us suppose the augmentation of colour by juxtaposition to equal one-tenth, its optical effect may be stated as 1¹/■■. If a single coloured uniform, by one year's wear lose one-tenth of its colour, it is clear that the uniform of the above two colours after being worn the same time will

be as effective as the single colour was originally.

Similar reasoning may be applied to all colours that are complementary, as orange and blue, violet and greenish yellow, &c.; it is necessary however to take into consideration their difference of tone.

Among colours which are not complementary, but which produce an agreeable contrast, may be mentioned particularly blue and yellow, blue and scarlet, green and yellow.

Blue and Yellow.—These two colours harmonize well, the blue imparting to the yellow an orange tint so much the deeper as the tone of the blue is raised, while the yellow communicates to the blue a beautiful tint of violet, or if the blue have any unpleasant greenish tint the yellow will neutralize it. If, however, there be a great difference in the tone of the two colours, contrast arising from this difference might destroy the effect of the contrast of colours; so that a deep blue might appear black or less violet, while the yellow, being enfeebled, might seem greenish.

Blue and Scarlet.—Deep blue and scarlet make a beautiful assortment, the blue giving fire to the scarlet; the latter rendering the blue more pure. There is no doubt that for effect a clearer blue and a fresh orange would be preferable, if there be no white in the uniform.

Green and Yellow.—This combination pleases by its gaiety, which suits cavalry of the line. But the green should be yellower and clearer than that which associates well with red; for the twofold reason that the yellow, by neutralizing a portion of the yellow in the green, raises the colour of the blue, and consequently lessens the brilliancy of the green. Besides, this effect tends constantly to increase, as the yellow of the green fades sooner than its blue. On the other hand, the yellow cloth receiving red from the green, must not be taken too deep. This case furnishes a good example of the economical advantage of contrasts of colour generally; and it will be seen that good arrangements are so much more difficult to make, as we depart from the contrast of complementary colour.

Of a single Colour and White.

We must refer to our preceding observations with respect to the juxtaposition of white with colours (178) to reason upon these combinations in uniforms. Colours are heightened, their complementaries are added to the white, and effects are produced which are so much the more perceptible as the colours are less raised in tone. If the white is rusty the juxtaposition of blue will heighten its tint; violet placed beside it will clear it, rendering it yellow; green will increase its redness; yellow, and especially orange yellow, will enfeeble it.

A white uniform has a good effect, not only when white pantaloons are worn with a white coat, or with facings, collar, &c. of white to a light coloured coat; but it has a good effect also with light trousers; for instance, light blue and white coat, or collar and facings. White trousers also do well with a uni-coloured coat.

Bi-coloured Uniforms with White.

White produces a really good effect only with blue and orange, or blue and red, being much inferior with green and yellow, or blue and yellow. It is, however, very suitable for trousers, with any combination of two agreeable colours in the coat. Nothing more clearly demonstrates the advantage of blue or red with white, than the difference between a uniform of deep red and blue without white, and the same with white facings and buff-skin belt, &c.

Bi-coloured Uniforms with Black.

Black enters advantageously into the composition of many uniforms of two luminous colours, such as scarlet, orange, yellow, or bright green. A scarlet coat with facings of greenish, rather than orange, yellow, is perfectly adapted to black trousers. And black trousers may be associated with sombre colours in the other parts of the dress for a uniform which is not to be conspicuous or seen far off.

Uniform of more than two Colours, not comprising Black and White.

Although three colours may be combined without producing a bad effect, yet I give the preference to a bi-coloured dress with a mixture of black and white. And I may remark here that if the sight of several colours be more agreeable than of one only, there are disadvantages in the union of many colours, especially if the colours are scattered on different objects, or several parts of the same object.

Uniform of several Shades of the same Colour.

Strictly speaking, it is possible to make an agreeable arrangement of colours belonging to the same or neighbouring scales; yet the difficulty of doing this, and the chances of success where there is a contrast of colour, determine me to reject the former, at least whenever brilliant colours are employed; but for sombre-coloured arrangements they may be employed. In proof of this, I will mention the bad effect of those French uniforms, in which there is a juxtaposition of madder and of cochineal reds.

Uniforms of two Tones of the same Scale.

This arrangement is not successful, for the lighter loses its colour, and if the deep tone acquire it, it is scarcely ever advantageous.[3] We will not therefore dwell upon it.

[3] It must be remembered that Chevreul speaks here of colours exclusively as to their optical effect, and that the very objection which he states to such an arrangement of colours, would be one of its best recommendations to the advocates of an obscure, in preference to a conspicuous uniform, as for Rifle Corps.

Of a Mono-coloured Uniform.

If uniforms of contrasted colours are advantageous in an economical point of view, if light coloured uniforms present advantages when it is desirable to exhibit to the enemy the numbers who oppose him, there are many cases in which the object is rather to conceal and dissimulate their presence, than to display them. Well, for such purposes, or if there is to be established a sort of hierarchy among the various corps, by means of dress, we may have recourse to a single and sombre-coloured uniform.

The Influence of Superficial Extent upon Combinations of Colours in Polychromous Uniforms.

I have already several times had occasion to speak of the influence of extent in the proportions of colours even when well associated, I must now add that it is not enough merely to make a satisfactory combination, but that _to produce the best results from colours, they must be employed in suitable respective proportions_.

When a colour is in feeble proportion to another, it must be spread as equally as possible throughout the garment; as, for example, in the uniform of the artillery, blue and scarlet; the latter, although far less in superficial proportion, produces a very good effect, because it is distributed throughout the uniform.

In a polychromous uniform, where one colour is found in several garments, we must avoid confounding the colour with the superposed or contiguous parts, so as to make one portion seem to belong to another. For example, the French regiments wear red trousers, with a blue coat turned up with the same red as the trousers. What happens? At a certain distance the one seems a part of the other, and the blue coat-tails seem far too narrow. It would be easy to remedy this defect by putting blue with red braid for the portions of the coat turned up.

From the above, I admit the two following principles:—1. Whenever the coat and trousers are of the same colour, and there is a second colour put upon the coat in feeble proportion, it must be repeated on the trousers, in a broad band, if the soldier wear boots, or in a braid, if he wear shoes. 2. Whenever the trousers are not of the colour which forms the basis of the coat, but of facings or distinctive parts, a band or simple braid of the main colour of the coat will restore to the trousers their distinctness.

* * * * *

These remarks show how desirable it is that the choice of colours, and especially of those which are distinctive of regiments or corps, should be the result of rules, established by their adaptation to the duties to be rendered by the regiments wearing them.

INDEX.

A. Aërial perspective, 83. Analogy, harmonies of, 48. Arabesques, varieties of, 164. Architecture, Egyptian, employment of colours in, 138; Greek, 139; Gothic, 141; application of colours to the interior of edifices, 143. AEOLUS

THE FUTURE OF THE FLYING-MACHINE

INTRODUCTION

The aeroplane is an aerial sailing-ship, its wings are the sails, its source of power the wind. It can claim to be a direct descendant of the family of sailing ships whose father was AEOLUS, god of the winds and the inventor of sails.

Aeroplane, helicopter, ornithopter, rotorplane, and autogiro are sailing-ships because they all derive lift from sails or aerofoils. An aerofoil is a structure so shaped as to obtain a reaction from the wind—a sail is nothing more and nothing less. Whether the wind is natural or is artificially raised by an engine does not affect the function of aerofoil or sail.

The heavier-than-air flying-machine, either engineless glider or power-driven craft, is the true aerial sailing-ship. The prolate gasbag which is called an airship resembles only one kind of ship, a sinking ship, because it is totally immersed in the fluid which supports it. If a sea parallel to the airship is required, that parallel may justly be said to be the submarine, which is suspended in the water as the airship is suspended in the air.

Before I deal with the future of the aerial sailing-ship I must define three aeronautical terms. No excuse is needed for introducing these apparently elementary definitions since aeronautical terms are almost as well misunderstood by aviators as by laymen. The three terms are:

Wing Airscrew Propeller

The definitions I advance are supported by the Royal Aeronautical Society's _Glossary of Aeronautical Terms_ and by the British Engineering Standards Association's _Glossary of Aeronautical Terms_ although they are often departed from in official forms and in speech.

Wing. A few days ago I read in a newspaper of a "single-winged airplane". Accustomed as I am to the aircraft which appear between the drapers' advertisements in the daily newspapers, I was startled at the notion of a "single-winged airplane". A bird has wings. A single-winged bird would be a queer creature and would be incapable of flying. A "single-winged airplane" would be equally queer and equally earth-bound.

The reporter, in trying to hack out an explanatory synonym for monoplane, docked the aeroplane of one of its wings.

Airscrew and Propeller. An aeroplane can have an airscrew yet no propeller. Most aeroplanes, in fact, are without propellers. In the interests of differentiation it is worth endeavouring to confine the word propeller to the thing that propels or pushes the machine, to use airscrew as a general term, and tractor airscrew when a precise definition is required for the thing that pulls the machine. The colloquialism "prop'" may perhaps be allowed to stand for both tractor airscrew and propeller.

In the following pages I make no attempt to hit upon any sudden invention which may revolutionize flight. I confine myself to developing lines of progress which have already given some proof of practicability. For determining the general trend of progress I rely upon a utilitarian review of the aeronautical situation. I have avoided leaping into the distant future. Readers will be disappointed to learn that things like inter-planetary voyaging are not dealt with in this booklet.

I am aware that scientists have demonstrated that some of the things I do mention are impossible. But scientists have demonstrated that the world is flat, that it is round, and that it is oblong. In the future they will demonstrate that it is rectangular. It was Mr W. N. Sullivan, I think, who said that "To judge from the history of science, the scientific method is excellent as a means of obtaining plausible conclusions which are always wrong, but hardly as a means of reaching the truth." While a few generations can still witness wide variations of opinion among those who know, I incline to the Pyrrhonic doctrine. It is impossible to know with certainty what is impossible, and in attempting a forecast the best that can be done is to take the trend of contemporary thought and, with that, to build a future upon the principles of the present.

I deal with the future of three kinds of flying-machine, the civil, the service, and the lighter-than-air or airship. The type of machine I say will become popular for short distance air-transport may seem at first to be too unconventional. But I think the whole trend of advanced thought (slotted wings, wingflaps, anti-stall gears and differential ailerons are manifestations of it) is towards the result I suggest.

I

The future of the aerial sailing-ship or heavier-than-air flying-machine will be affected more by the attitude which the world adopts towards it than by technical achievement. In England the national attitude towards machinery is moulded by statesmen and financiers. Under the guise of preserving the liberty of the individual that attitude strangles the life out of the machine; it may be described in the words of the schoolboy who said that _Habeas Corpus_ was a phrase used during the great plague of London meaning 'Bring out your dead'.

The statesman has helped to mould the national attitude towards the motor-car through the medium of laws and the manner of their enforcement by his servants the police, and the Courts. The history of the cause and effect of the national attitude towards the motor-car is being repeated with the flying-machine, and the parallel is close.

Having the safety of the public for its ostensible object, the Motor-Car Act limits the speed of motor-vehicles to twenty miles per hour, proclaims it an offence to drive to the common danger and to be drunk while in charge of a motor-car.

Of the last-mentioned provision I will say nothing beyond mentioning that there are motorists who are incapable of driving safely except when they are drunk. Of the other two, the 20 m.p.h. speed-limit for many years has been generally recognized as having

no bearing on safety or danger, whereas for many years motorists have been condemning certain manoeuvres on the road as constituting, legally as well as in truth, driving to the common danger.

The English police, with the connivance of magistrates and Home Secretaries, have concentrated on enforcing the speed-limit and have ignored the dangerous manoeuvres.

This pass has been brought about by the statesman, who has no direct interest in motor-cars or other new-fangled machines (except when there is a general strike). As a consequence, the car built as a car for speed and control is becoming an object of general dislike. The continued insistence that speed of itself is dangerous and the pompous tyranny of the police (who find motorists tamer and more plastic than thieves) are gradually engendering in the public fear of and dislike for the machine-entity. Instead the wheeled furniture-shop is gaining in popularity. The doctrine of Safety First is threatening initiative and killing the spirit of adventure, while there is ignorance of how to attain safety. Road-racing, the only sure means of increasing car-safety, is prohibited because it is not safe. The result is the dismal, abysmal mess described as the modern British motor-car, which is chiefly remarkable for not containing a single original idea.

Now the result of statesmen moulding a similar attitude towards the flying-machine will be equally dismal. Yet they are already exerting their influence in that direction.

Instead of employing policemen and Courts to harry and hunt the herd of aeronauts, designers, and constructors, however, the statesman employs an army of air-officials. In the world of aeronautics these officials are all-mighty. The private person has no control over them and no reply to them. If he goes to Court against them he will lose. If he appeals against the decision of the Court he will lose again. If he appeals to public opinion he will lose for the third time. The official tells the airman what he may not do, warns the designer of the manner in which he may not design, and informs the constructor how he is forbidden to construct.

The result of this official attitude towards the flying-machine is already faintly visible.

At the time I write Britain holds no world's air-records. For seven years she has made no great flight. She has three or four commercial air-lines against Germany's forty-three. Her fastest aircraft is about 50 m.p.h., slower than the fastest foreign aircraft. Her highest climbing aircraft cannot attain within thousands of feet of the altitude attained by foreign aircraft. Her longest range aircraft can accomplish little more than half the distance covered by foreign aircraft. Her Air Force can put fewer effective war-machines in the air than any one of three other countries.

One of our pilots has succeeded in proving that, in an English aeroplane, you can go from London to anywhere else more slowly, and in more acute discomfort, than by boat and train.

In one thing only does England excel. She spends more on aviation than any other country in the world.

I am familiar with the excuses for England's aeronautical failings. I know that the House of Commons has been told that there is no object in England attempting to obtain world's air-records. I have heard the claim that the Royal Air Force flies more than any other air force, and I have heard the Air Ministry refuse to supply any figures in support of the claim. I know that the French are said to obtain their high speeds and great distances by cutting down the load-factor of their machines. I have been told about the theory that we _could_ gain world's records, run air-lines, win air-races, and have an effective Air Force but that we do not want to do so. I am familiar with these excuses, and, having mentioned some of them, I think I can proceed to indicate a cure for the failings in British aviation. For some cure is the essential preliminary to any future for the flying-machine in England.

The cause of England's aerial impotence is chiefly official interference leading to a wrong national attitude towards the aeroplane.

The cure is to give English aviation the freedom of the air.

If the official is given powers to make vehicular transport safe, he will, as we have seen in the motor-car analogy, infallibly not make vehicular transport safe and he will stop any mechanical development in the vehicle itself. Freedom, then, is the essential condition of aeronautical development.

I said at the beginning of this essay that the financier, as well as the statesman, helped to mould the public's attitude towards the machine. I speak only of the pure financier or business-man who uses aeroplanes, motor-cars or tin cans with equal indifference as money-making tools; who has no direct interest in any material creation; who repeats that honesty is the best policy and hopes the other man will believe it.

All such business-men in England are humble imitators of American business men. In their advertisements, offices, talk, and indigestion they endeavour as closely as possible to copy the Americans. They therefore believe that, if English people are to produce cars or aeroplanes, they must produce them in the American way—that is cheaply and in mass. Standardization has, in their view, taken the place of craftsmanship and mass-production of hard work.

Already events have shown that the English are incapable of imitating the Americans well. The reason is that the American mechanic regards his work as an unpleasant necessity, to be got through as quickly as possible and to be paid for at as high a rate as possible in order that he may have time and money for the real purpose of life—doing nothing. The English mechanic, although the statesman is trying to knock such foolishness out of him, still expects to find something satisfying in his work. He still seeks a measure of contentment in the exercise of skill.

Mass-production fits in well with the American workman's ideas: it does not fit in with the English workman's ideas. The English do not and will not produce cheap motor-cars or cheap aeroplanes as quickly and as well as the Americans.

If English flying-machines are to be made capable of competing with American and others, the English, after being freed from official interference, must leave standardization and mass-production to people who are temperamentally suited to them, and instil into these flying-machines some of the idiosyncrasy of their race. Their flying-machines must be creations expressive of the characters of those who design and construct them.

The only English cars having any success in America (and elsewhere) are those few in which perfection of craftsmanship and idealism in design are notable. They are the kind of cars English designers and mechanics are temperamentally able to produce. The mass-produced cheap English car or flying-machine will remain a feeble imitation of the American. But the idealistic creation, the machine-entity of the English artist-scientist in car or flying-machine has a place to itself in the scheme of things. In its best form it is unique.

The financier's influence in aviation is not yet so noticeable as in motoring, but it is becoming stronger. Should the aeroplane pass entirely into his hands, it will cease to progress as a flying-machine and will start progressing as a bank-note churn. With the future of such an instrument I am unable to deal, since I have no personal experience of either churns or bank-notes.

If it is to make headway as an individual creation the flying-machine must receive the freedom of the air. It must develop its own individuality as a machine-entity. Freedom of the air and the complementary institution of mechanical craftsmanship are the essential conditions for development of the flying-machine. Without those conditions I have nothing to write of its future. With those conditions the flying-machine presents possibilities of development in high-speed transport that will warrant future generations describing the present age as the static age.

But I must insist that, for the forecast I am now to make, I postulate the gagging and binding or otherwise bottling-up of the statesman and financier.

Only then will this machine-entity, the creation of the artist-scientist, grow. And that the machine-entity, the car or aeroplane as a real and living thing exists will be accepted by all who have spent much time in controlling and looking after high-performance aeroplanes or racing-cars. These machines, built with a single purpose, are sensitive to the treatment they receive as the stone is sensitive to the sculptor's chisel or the violin-strings to the musician's bow.

Turn for one moment from the standard cars, the wheeled furniture-shops "replete with every comfort including cigarette lighter and flower vase" which make hideous our streets to the other extreme and regard the finely-wrought, aesthetically satisfying racing-car which is to be seen in the American and Continental road-races and occasionally at Brooklands. I do not suggest that racing-cars should be used for transport even in these "most brisk and giddy paced times"; I merely refer to the racing-car as indicative of a certain attitude towards the machine. The makers of flying-machines should be free, if such is their desire, to aim at the fineness, craftsmanship, and originality in design exemplified in the racing-car.

II

The civil flying-machine, when it is examined in the light of contemporary aeronautical research-work, seems rich in possibilities.

Apart from electrical repulsion, there are five different ways of flying, of which only two are at present in general use, lighter-than-air flight and fixed-wing heavier-than-air flight. I think that a third method is about to be widely adopted, and that this third method will,

in time, profoundly influence the whole future of aeronautics.

A comparison between the present system of artificial flight and natural flight will suggest what that third method is.

Let us go to Croydon, the airport of London, and examine a typical three-engined passenger-carrying aeroplane.

The three engines are running, for the machine is about to take off. The coffin-shaped thing whose sides flap in the wind from the airscrews is the fuselage. The machine shows signs of malnutrition, for its bones are prominent in the form of wires and struts. As the engines are run up, the tail shakes and sneezes and coughs until it seems that the fuselage will be ruptured. Now the machine taxis over the aerodrome, its engines open up with a roar, it labours over the ground, and then, looking a little fatigued, it rises into the air.

It passes overhead making a noise like a thunderstorm, shivering and quaking, barging its way along with a clumsy ineffectualness which gives it the appearance of flying through treacle.

When it is out of sight, go to Waterloo Bridge and watch the gulls.

A gull is a hopelessly uncommercial flying machine. It does not pay, it has no ground organization, it is not fitted with wireless, no control-tower informs it when it may land, no books are kept of its mileage or hours flown, no managers, assistant-managers, clerks, secretaries, typists, accountants, ministers, directors, officials, or meteorologists concern themselves in its safety. No offices, search-lights, flood-lights, neon-lights, leader-cables, or directional wireless stations are set aside for its control and supervision. No treatises are written about its future. A gull is not “a commercial proposition”. It is, however, a good machine for flying.

Neither the superficial nor the fundamental defects of the passenger-carrying aeroplane are present in the gull. The gull is a coherent, unified structure without exposed bracing-wires, struts, or engines. It gets off quickly, flies at a great pace (for its power-loading), is fairly silent and very manoeuvrable, can defeat fog, rain, hail, snow, and gale, and can alight anywhere.

As a flying-machine it owes its basic superiority over the aeroplane to a single, ingenious trick: a trick which looks easy, but which, for many years, the scientist found it impossible to reproduce in practical mechanics.

When flying was first thought about this trick engaged much attention. The mechanical difficulties in reproducing it, however, refused to be conquered, and about 1680, Borelli, having this trick in mind, wrote: “The Icarian invention is entirely mythical because impossible”, a view which, according to Mr J. E. Hodgson’s _History of Aeronautics_, was supported by Leibnitz. Afterwards and until just recently the trick has been almost entirely neglected. I think it probable that it will regain its old importance, and that it will become the pivot upon which the whole future of the heavier-than-air land-going flying-machine will turn.

What is this trick which for centuries baffled the mechanician, yet which the gull finds so simple? What is the one fundamental difference between the means employed by the gull for flying and the means employed by the aeroplane?—It is the difference between the fixed wing and the moving wing.

The gull has the trick of being able to move its wings relative to its body. The gull is a moving-wing flying-machine. The conventional aeroplane is a fixed-wing-flying-machine.

Almost every important advantage which the gull (and any other bird) has over the type of aeroplane which has so far been most popular may be traced to the gull’s ability to move its wings. For that reason alone it can get off without a long run, defeat fog and gale, and alight anywhere.

Since the time of the artificial “flying pigeon” of Archytas in the 5th. cent. B.C. the manner of whose flight seems obscure, attempts have been made to build machines which imitate the gull by flapping their wings. Several people, including Bladud, the legendary flying King of Britain, found out in an unpleasant manner that the muscles were not strong enough to actuate man-lifting wings. And in the construction of engine-driven ornithopters the mechanical difficulties invariably proved insuperable. The natural flapping wing has never been exactly imitated by mechanical means in a flying-machine, nor have the leg and foot been exactly imitated by mechanical means in a motor-car.

The motor-mechanician, in using the wheel in place of the leg and foot, imitated the principle employed by nature for land-locomotion but not the means. Will the aeroplane-mechanician imitate the principle employed by nature for flight but not the means?

The aeroplane-mechanician has already accomplished this feat in a rudimentary form in the Cierva Autogiro, which is commonly (and accurately) called the windmill aircraft.

The helicopter has never achieved much success and, for the present purpose, it may be classed with the ornithopter as obsolete. The autogiro, therefore, is the first practical moving-wing aircraft. It accomplishes that which generation after generation of mechanicians found it impossible to accomplish. It has seized on the bird-principle of flight and translated it into practical mechanics.

III

The existing autogiro, although it may not resemble the more developed types which will eventually appear, is the most successful moving-wing flying-machine yet produced. Señor de la Cierva's work was described by an aeronautical engineer as being of secondary importance only to that of the Wright brothers. That first flush of enthusiasm may be over, but there seems little doubt that future generations will regard Señor de la Cierva as the inventor of moving-wing flight. And I believe that there will be a fierce battle, more prolonged and more vigorous than has ever been fought between two machines, the battle between moving-wing flight and fixed-wing flight. The struggle between reciprocating engine and turbine, broad gauge and narrow gauge, lighter-than-air and heavier-than-air, water-cooling and air-cooling will be as nothing compared with the imminent struggle between fixed-wing and moving-wing.

The autogiro obtains lift from a _free_, four-bladed windmill. Each blade of the windmill is a wing and is articulated at the root so that its tip can rise and fall. The autogiro is drawn forward by an ordinary aero-engine and airscrew which are entirely separated from the windmill. As the machine is drawn through the air the relative wind, blowing on the blades or wings, rotates the windmill and it lifts the machine. The wings rise and fall, and this beating motion gives the machine a measure of stability.

To exert lift a wing must move through the air.

The moving-wing aircraft derives lift from wings which can move through the air even though the body of the machine be stationary or nearly stationary. In the fixed-wing aeroplane both body and wings must move if the wings are to exert lift.

[Illustration:

Fig. 1.—Diagrammatic representation of moving-wing and fixed-wing flight. The wings of both machines have travelled equal distances AA and BB but the body of the moving wing machine has remained stationary relative to the ground.]

The difference between moving-wing and fixed-wing aircraft is so important to this discussion that I shall venture to describe it again in different words. A fixed-wing aircraft is like a bird with its wings paralysed or in splints. A moving-wing aircraft is like a bird having the full use of all its faculties. (Fig. 1).

Perhaps the most important advantage which the moving-wing aircraft has over the fixed-wing aircraft is that it can virtually land on one spot. The conventional aeroplane must move forward in still air if it is to keep up; it must still move forward while landing, and afterwards allow its impetus to be dissipated during a run along the ground.

In addition to this ability to land on a spot, the moving wing aircraft is less likely to become uncontrollable while it is in the air. The fixed-wing aircraft must become uncontrollable in the air if its speed drops below a certain point. This point was called by airmen "the stalling speed". It has needed the mathematician to produce the phrase: "control of stalled aeroplanes". In current English a stalled aeroplane is an aeroplane which is uncontrollable, even if the speed must drop to zero before this condition arises. If any fixed stalling-_angle_ can be said to exist outside technical reports, it is the angle at which the lift of the wings is so reduced that the machine must fall to a nearly vertical position before recovering.

The moving-wing aircraft in the rudimentary form we know it to-day could stall, but it would need a major structural failure or violent and prolonged misuse of the controls to make it do so.

And now one of the weapons which will be used in the battle which I predict between the two main types of heavier-than-air flying machines will be recognized. The weapon of the spot-landing.

Taking advantage of its special characteristics, the moving-wing flying-machine within fifteen years will open hostilities by carrying passengers into and from the hearts of cities and by running safely through fog thick enough to stop other transport services. Up till

then the fixed-wing machine with its aerodromes on the outskirts of cities will have held the field almost unchallenged. But whereas the fixed-wing aircraft has now had twenty-two years development, the moving-wing aircraft has had only about three years.

At first, even when it has matured, people will be shy of the moving-wing machine, and only gradually will it begin to attract passengers used to the other type.

Travellers will begin to realize that, when they go by fixed-wing machines, they waste so much time and suffer so much discomfort in the terminal communications that the advantages of the air-passage are largely neutralized.

At present the air-traveller going from Paris to London spends one and a half hours covering the few miles to and from the aerodromes to the centres of the two cities and only two to two and a half hours covering the 225 miles of the air-journey. Moreover, he changes vehicles twice, at Croydon and at Le Bourget, as he does by boat and train at Dover and at Calais. The aircraft's ability to fly over land and sea alike, therefore, has not given the traveller the advantage of a through-journey. He must taxi from his hôtel in Paris to the place where the air-company's car starts, change from car to aeroplane at Le Bourget, change from aeroplane to car at Croydon, and taxi from the car's stopping place to his home. (Fig. 2).

[Illustration:

Fig. 2.—Diagrammatic representation of the advantage in flexibility of an aircraft capable of making spot landings and so of using small aerodromes. Alone among vehicles it could provide a through journey to the centres of cities.]

The aeroplane dare not risk attempting the journey in thick fog or heavy snow or hail because, in order to support itself, it must move forward through the air at a minimum of say 60 miles per hour. At this speed the pilot, even if aided by a leader-cable, has difficulty in finding the aerodrome in thick weather; as much difficulty as a motor-car-driver unable to go slower than 20 miles per hour would have in crossing London in a dense fog.

If he thinks he catches a glimpse of a landmark, the pilot cannot stop or slow down and look again to confirm his impression; he must continue to travel at 60 m.p.h. And if he fail to find the aerodrome he must endeavour to put down his machine—still travelling at 60 m.p.h.—on an area of ground which he cannot see clearly and which he does not know. If a house, ditch, hedge, tree, chimney, shed, road, telegraph wire, pole, or other obstruction is in the way the result is a serious accident.

The disadvantages under which the fixed-wing aircraft suffers when landing and when flying during bad visibility are inherent in the principle of flight it employs. The moving-wing machine will therefore concentrate its attack at these very points. Since it is able to fly slowly, and virtually to hover, it can feel its way through fairly thick fog. Even if the pilot cannot find the aerodrome, comparatively little danger attaches to a forced landing on unknown ground, because the descent can be made vertically or almost vertically and there is almost no run after touching the ground.

Aerodromes on the roofs of buildings have been foretold with tiresome persistence. A Frenchman succeeded in landing a fixed-wing aeroplane on a roof in Paris. Even so I cannot foresee roof-aerodromes for fixed-wing aircraft, which is the purpose for which former prophets have foreseen them; but I emphatically can foresee roof-aerodromes for slow-landing, moving-wing aircraft.

Travellers going by future air-lines will take a taxi from their homes to Charing Cross, step into a moving-wing machine on a roof-aerodrome, fly to Paris, land on another roof-aerodrome near the Place de l'Opéra, and take a taxi to their hotel.

I think it likely that, by the time it reaches maturity, the full speed of the moving-wing aircraft will be below that of the fixed-wing aircraft. But it will make up for this disadvantage by offering travellers the advantages of eliminating terminal communications and changes of vehicle. Part of the time it loses between Croydon and Le Bourget it will regain between Croydon and Charing Cross and between Le Bourget and the Place de l'Opéra. Moreover, on days when, through fog, the fixed-wing aircraft-service is suspended, the moving-wing aircraft will still operate.

By these means the moving-wing aircraft will become a formidable competitor of the fixed-wing aircraft. How will the fixed-wing aircraft reply to the attack?

It will make a supreme effort to increase its speed to such an extent that it will offer to travellers a journey taking from door to door only about two-thirds of the time occupied by the other type. To do this the time lost in terminal communications by motor-car will, at first, be partly recovered by extremely high flying speeds. The 250 miles per hour air-express will make its appearance. The wing-loading of these machines will be high. Dr Rohrbach the German designer, believes that great advantages accrue through

high wing-loadings, and in lectures and papers he has described at length the reasons for his belief. In order to get these highly loaded machines off quickly and to land them within an aerodrome of reasonable size, a form of catapult launching apparatus and an arrester will be employed.

Catapult-launching has been proved, in England, America, Italy, and France, to be practicable with fairly large aircraft. There is no reason to suppose that its development will not continue.

An aircraft-arrester was described by Mr G. H. Dowty in a paper read before the Institution of Aeronautical Engineers in October 1926. It consisted in a drum having wound round it a length of cable. The aeroplane, by some hook and line device similar to that used by Army co-operation machines in picking up messages, will connect itself to the end of the cable. The cable will rotate the drum against a brake, and the aeroplane will be arrested. Mr Dowty calculates that a machine travelling at 90 m.p.h. could by this means, be brought to a standstill in 100 yards without an excessive strain being put on the machine's structure.

The chances of forced landings in these highly loaded fixed-wing machines will be reduced to a negligible quantity by big reserves of power and by providing that power through many engines.

In spite of the acceleration of the fixed-wing services made possible by the use of these express-aeroplanes, the popularity of the moving-wing services will continue to grow. The public will count time well lost against the discomfort of changing twice and motoring long distances through roads as inadequate for the traffic of that day as the existing ones are for the traffic of this. They will continue to take taxis to the Charing Cross roof-aerodrome when they want to travel by air to Paris, York, Manchester, Glasgow, or Dublin.

The drifting of passengers to the moving-wing services will spur the supporters of the fixed-wing services to devise another reply. They will build motor speedways from Croydon reaching into the heart of London and from all the other big aerodromes into the hearts of the cities they serve. These speedways will have no side-turnings or cross-roads. They will be forbidden to pedestrians, bicyclists, lorries, 'buses, and similar vehicles. They will be hedged in on either side like railway lines. The flat-footed influence of policeman and politician will be excluded and along these tracks cars will carry passengers to and from the aerodromes at 100 miles per hour. Assisted by these tracks, the great speed of the fixed-wing services will temporarily prevail, and a fair supply of passengers will be assured although the moving-wing services will still flourish.

The position at this stage of the battle might be described as a deadlock. The next stage will perhaps be the most remarkable of all.

It may have been noticed that, unlike most prophets, I have been exceedingly modest in naming the distances over which these future services will operate. While discussing the battle between fixed-wing and moving-wing, instead of speaking of Empire services, Globe-circling airlines, or non-stop hemispherical flying expresses, I have spoken of trivial routes like London-Paris and London-Glasgow. I have not even mentioned London-Karachi, London-Melbourne, or London-Montreal.

My modesty was only temporarily assumed. I am now about to throw it off in order to describe what I believe will be the most important development of the flying machine. This development will begin during the latter part of the fixed-wing, _v._ moving-wing battle.

IV

I have spoken, in describing the fixed-wing versus moving-wing battle, only of short air-lines, because I think the establishment of the successful short line will precede the establishment of the long.

It is argued that the saving in time effected by the flying-machine becomes valuable only in long journeys, so that no one would bother to go to an aerodrome and take an aeroplane in order to save half an hour or so, and that the train-service in England is so good that the aeroplane-service would be incapable of competing with it successfully. And, while the disadvantages of short air-services are magnified, the disadvantages of long air-services are forgotten or not appreciated.

At present a short journey of three or four hours by aeroplane is all that the average passenger can stand in comfort. There is no room for him to move about much in the present cabins, and the noise of the engines, wires, and airscrews is fatiguing to anyone not used to it. Moreover, the time-basis is not the only basis on which the traveller compares the merits of the means of travel at his disposal. The ship provides its passengers with social intercourse and a high degree of comfort. A long journey by sea is usually a pleasant, invigorating experience. On a journey by air, on the other hand, the passengers get no fresh air, they have no opportunity

for making friends, for conversation, dancing, games, or any other of the fascinating trivialities which flavour life on board a passenger-steamer. The traveller offered the use of a long distance air-line, therefore, is invited to choose between, perhaps, three days discomfort and isolation in the cramped cabin of an aeroplane and three weeks social pleasure and invigorating laziness on board ship.

Now the disadvantages which attend long-distance air-travel in modern type machines are due almost entirely to the small size of passenger aircraft when compared with ships. The aeroplane will not be successful as a long-distance vehicle until it can give its passengers most of the pleasures they would get on board ship. It will not be able to give its passengers even a small fraction of those pleasures until it is as large as or nearly as large as the ship.

The pleasures of long-distance travel vary almost directly as the size of the vehicle. Can the aeroplane ever be made so large that it can offer its passengers the space and freedom of even a small-sized passenger-boat?

I do not think the aeroplane can ever become sufficiently big, but I do think the seaplane or the flying-boat can and will become sufficiently big to offer that degree of space and freedom.

I believe that aircraft will begin to compete successfully with boat and train in carrying the merchandize and passengers of the world only after the coming of the era of the hydro-aeroplane (I use this word to include both seaplane and flying-boat).

The longest flight ever made in one machine was made in a hydro-aeroplane. The largest machines ever built are hydro-aeroplanes. The heavier-than-air machines carrying the greatest weight are hydro-aeroplanes. I am confident that the era of the hydro-aeroplane will come, and that, until it comes, aircraft will not compete successfully with boat and train.

I have based my first conclusion, that the moving-wing aeroplane will become a powerful competitor of the fixed-wing aeroplane for short-distance air-transport, on flexibility. The moving-wing machine can go from door to door, no matter if the journey is partly over the sea and partly over the land. I base my second conclusion, that the hydro-aeroplane will become the pre-eminent vehicle for long-distance air-transport, on size. The hydro-aeroplane can be built as large as may be required.

If people are to journey even for one day in the same vehicle, they need space and freedom of movement. They need wide promenade decks, lounges, restaurants, cabins, smoking-rooms. They cannot be confined to a single basket chair.

For long-distance air-transport the sardine-theory so popular with our London transport controllers must be abandoned. The sardine-theory must be recognized for what it is, a system of getting more money out of the passenger by increasing his discomfort. The more you squeeze the passenger, the more the money oozes out of him.

The aeroplane cannot, I think, become very much larger than the largest machines of to-day because the support of much greater weights on the landing-wheels becomes difficult. At present there are machines in which each landing-wheel must carry 6 tons. If the weight were much increased, the three-point suspension on wheels and tail-skid would become impracticable. The provision of a caterpillar landing-gear and of aerodromes with prepared surfaces might be possible and might assist matters if machines, say eight or nine times the size of the present, were contemplated. But, to obtain the comfort required (and given by the ship) on a long voyage, the machines would need to be some fifty or a hundred times the size of the largest existing types. When those sizes were reached, the problems of supporting the weight on the ground and of manoeuvring on the ground, taking off, and landing would become exceedingly difficult to solve.

Yet these problems are comparatively easy to solve in the large hydro-aeroplane. A large hydro-aeroplane with a high wing-loading could, if necessary, use the open sea as its aerodrome. Since the problem of the forced landing would definitely have been overcome by the power-unit arrangement, the large hydro-aeroplane would fly over land or sea. Its stations would be sea ports, lakes, or wide rivers.

The aeroplane both with moving and fixed wing will certainly grow in size; but nothing seems to me to indicate that it will be able to keep pace with the growth of the hydro-aeroplane. The growth of the hydro-aeroplane is foreshadowed in a French machine and a German machine which have appeared recently. The hundred-passenger hydro-aeroplane is a proven possibility. I can see no insuperable obstacle to the eventual arrival of the 1,000-passenger or the 2,000-passenger hydro-aeroplane. Moreover, the fog-landing problem is easier to solve in the sea-going than in the land-going fixed-wing aircraft. Good automatic landing devices are more easily designed for hydro-aeroplanes than for aeroplanes.

Mr O. E. Simmonds, of the design staff of a firm of British flying-boat constructors, said: “The largest successful flying-boats yet built have weighed about 30,000 lbs. I shall certainly feel that progress has been inordinately slow if we have not constructed a boat of 100,000 lbs. gross weight _by the end of the next decade_.”

The first real air-liner, carrying some five or six hundred passengers, will probably appear after or towards the end of the battle between fixed and moving-wing machines. And it will be a flying-boat. The unsolved problems attending high-altitude air-transport seem to be so difficult that I am inclined to believe that high altitude transport will not become a regular method in this generation.

The possibilities of machines capable of travelling at immense speeds in the rarefied air at a height of 15 miles or so from the ground are attractive. But, if a forecast is to be based on research-work actually accomplished at the time, it is made, then high-altitude flying must be excluded.

Among the problems which high-altitude flying involves and which seem to postpone its arrival to the distant future are: the infinitely variable pitch airscrew, the light, positive, infinitely variable gear (without ratchet final drive), the sealed cabin with self-contained ventilating system, the engine altitude supercharger, and the variable camber-wing. Among these the Leitner automatic infinitely variable pitch airscrew is one of the most interesting inventions ever made in airscrew design, but it is at present in its earliest stages. The Constantinesco torque-converter, which is an automatic infinitely variable gear, might be adaptable to aircraft. The sealed cabin presents great practical difficulties, as does the variable camber-wing.

From this brief parenthesis the difficulties of high-altitude transport will be apparent. It is almost certain to come, but its day is likely to be distant, and for that reason I have concentrated on possibilities less remote.

Now that the long and short distance air-liners have been dealt with, I will give a brief sketch of how the traveller will use these vehicles. If Mr X, who lives at Hampstead, desires to go to Melbourne, Australia, he will first pile his luggage onto a taxi and drive to the terminus of some moving-wing aircraft line. This terminus will be close to the centre of London: A highly developed moving-wing aircraft will take him to the coast. The machine will land on the quay beside which will float a flying-boat express. This machine will be a fixed-wing flying-boat of about 1,000 tons. It will be a monoplane, the wings growing from the hull at a sharp dihedral angle and then curving down until they are horizontal.

The engines will be particularly interesting. Most designers, even now, are endeavouring to eliminate reciprocating motion in petrol-engines. The trend of thought is towards substituting the sleeve-valve for the poppet-valve and towards increasing the number of cylinders. More and more inventors “invent” gas-turbines. Their engines have had varying degrees of failure, although a few, the Jean Mély turbine among them, are reported to have gained a measure of success. One of these inventors will soon be completely successful. The movement towards the rotary gas-engine is too vigorous and too general to remain for ever unfruitful. The gas-turbine will be the aero-engine of the future. It will be cooled by an evaporative system.

One pound of water carries only 20 B.T.U., whereas 1 lb. of steam carries 966 B.T.U. Wing Commander Cave-Browne-Cave, in a paper read before the Royal Aeronautical Society, drew attention to the advantages for aircraft of evaporative engine cooling. He said: “By far the lightest way of conveying heat is as the latent heat of steam.” On test a standard aero-engine gave the same power and fuel-consumption with evaporative as with water-cooling. The greatest advantage will accrue in reduction of resistance. Panels in the aircraft surface will receive heat in the steam and thus the drag caused by water-radiators even of the wing or strut type, or air-cooled cylinders will be eliminated. The evaporative cooling system will not freeze up at the highest altitudes: it will probably maintain the engine at a more even working temperature than an air-cooling system, and the steam will provide a suitable means of heating the passenger cabins and pilot’s cockpit and of cooking.

The flying-boat to which Mr X is now having his luggage transferred then, has twelve evaporative-cooled gas-turbines housed in the wings, six on the starboard and six on the port side. Eight of them will drive tractor airscrews and four will drive propellers through torque-converters. There may be a system of concentrating the whole engine-power at three or four airscrews.

The entire machine, including the wing-coverings, will be built of metal. “I cannot conceive”, said M. Dewoitine, the French designer, “that the ultimate aeroplane can be in anything else but metal, in the same way that metal ships to-day completely replace the wooden ships of days gone by.” The living quarters in the hull would be arranged on labour-saving lines. The passengers would have drawing-room, dining-saloon, lounge, and promenade deck. The promenade deck on a long-distance air-express will be different from the promenade deck on a liner. It will be enclosed in the hull and will be lighted by a transparent roof and sides.

Mr X finds his cabin arranged in much the same way as in a ship, and, having settled his things, he goes up to the lounge, where the other passengers are congregating. A few minutes later, with a faint hum, two of the tractor-airscrews begin to revolve, and the flying-boat moves slowly away from the quay. Two more airscrews start revolving, and the machine, having taxied out, turns into wind. It pauses a moment as if it were taking breath, then the twelve air-screws spin faster and faster until they appear as discs of light. The machine moves forward heavily, a solid mass of metal, with the passengers watching from the windows of the promenade deck. It lumbers through the water, but throws up but little spray. Then it seems to stretch itself, throw back its head, and to rise bodily out of the water until it runs on the surface of—instead of in—the water. Already it appears lighter and less clumsy. Finally, after giving the water two or three parting pats, it takes to the air and, in spite of its great mass, instantly becomes an agile, graceful flying-machine.

The usual amusements, the usual eating, drinking, reading, and talking will employ the passengers' time in the air. For the daily round goes on in much the same way ashore, afloat or aflight. The night flying is exhilarating, although there is, of course, almost no sense of speed. Though the sea is rough, the machine, at 4,000 ft. is as steady as a rock. As the first stopping place rushes towards the machine, the hum of the engines alters note and the machine dips in a gentle glide. The mouth of a river, with shipping on it and two more flying-boat expresses lying at a quay a short way up the river, comes into view. The machine wheels round and glides closer and closer to the water. Four of the airscrews give a short burst of speed, and then the hull rips the surface of the water with a hiss.

Soon afterwards Mr X has said good-bye to his voyage acquaintances who are disembarking, and the machine is off on the next stage.

The success of the large, long-distance flying-boat will mark the beginning of the concentration of fixed-wing machines on long-distance routes and the concentration of moving-wing machines on short, distance routes. The fixed-wing machine, finding it has no rival in the large flying-boat type and finding that it has a strong rival in the comparatively small land-going type (that rival being the moving-wing machine) will gradually remove itself from the short air-lines. The position will then be that all short air-lines are run by moving-wing land-going aircraft while all long air-lines are run by fixed-wing sea-going aircraft.

The real air-liner, as distinct from the commercial flying soap-box of to-day, will be an immense sea-going air-vessel. It will be a self-contained town offering greater attractions to the pleasure-seeker than any other kind of small town. When that machine makes its appearance the Air Age will have begun.

V

Before I described the passenger-carrying flying-machine towards which contemporary research-work seems directed, I postulated the freedom of the air for that machine. I stipulated that the statesman and the financier should be gagged and bound. Now that I come to private-flying and air-racing, however, the imagination jibs at the notion of a similar freedom of the air. If the statesman were prevented from meddling with the technical development of the passenger-carrying flying-machine, he would most likely turn with redoubled vigour to the task of controlling, organizing, watching over, regulating, and generally bleeding the private, the record-breaking, and the racing aircraft.

I can, therefore, sketch the future of those machines only as the statesman will direct it.

The small fixed-wing private flying-machine, especially in the amphibian form, will gradually become more and more popular and, as it grows more popular, so the statesman will take more notice of it. His first opportunity for direct action will come when a few people get killed in an accident involving a private aircraft.

Taking advantage of the Press outcry, of the screams of the Safety First societies and of the opportunity for personal aggrandizement, Members of Parliament will pass a Flying-Machine Act.

Among the provisions of this Act will be a 40-miles per hour minimum speed-limit. No heavier-than-air craft will be permitted to fly at a speed of less than 40 miles per hour. It is easy to follow the workings of the official mind in setting this speed-limit. A fixed-wing aircraft crashes not because it goes too fast but because it goes too slowly. Therefore, the statesman will reason, if it is illegal to go too slowly, there will be no more accidents.

Another provision will make it illegal for anyone suffering from nicotine-poisoning to be in charge of a flying-machine. (Prohibition will be established in England by this time, so that no clause about "drunk in charge of a flying-machine" will be necessary.)

Further regulations will make it necessary for every private pilot to pass a medical examination once a month as a condition of his having a pilot's licence. Having passed this examination, he will be required to wear, while in charge of an aeroplane, two 8-inch metal discs, with a number stamped upon them. One disc will be worn on the left shoulder and the other on the top of the flying-helmet.

The aeroplane, in addition to its letter markings on wings and fuselage, will be required to exhibit three plaques bearing identification-numbers. One will be on the centre section, one on the undercarriage, and one on the port side of the fuselage. The aeroplane will also carry metropolitan or county police markings on four tablets of given size, besides markings of the appropriate local council on plates of certain specified dimensions, and small circular pieces of paper contained in approved holders on the rear port interplane-strut (or wing-tip in the case of a monoplane), the rear starboard interplane-strut (or wing-tip) the undercarriage port forward-strut, the tail-fin, the fuselage, and the top plane gravity-tank (if any).

In addition to the pilot's logbook, machine logbook, engine logbook, pilot's licence, and airworthiness certificate, there will be a registration-book, travel-triptych, flight-permit, landing-permit, and housing-pass.

These items are, of course, extra to the navigation-lights, wing-tip flares, cockpit-illuminants, parachute-flares, fire-extinguishers, silencers, life-saving parachutes, and other obligatory equipment, such as lifebelts, fire-proof bulkheads, stall-indicators, warning-signals, and Very lights.

These regulations will provide the police with the opportunity of displaying their keen sense of duty. They will ignore the old-fashioned and mundane murders, and will say with Horace Walpole: "Do not wonder that we do not entirely attend to the things of earth; fashion has ascended to a higher element."

Conceive the vigour and elegance with which they will uphold the 40 m.p.h. minimum speed-limit. What their stopwatches (for they will still use them) and observation lacks in accuracy, they will make up for by the free imagery and sweeping poetic fancy of their evidence in Court.

The pilot who flies while suffering from nicotine-poisoning will be the object of universal opprobrium. His social doom will be sealed when the witness says that his breath _smelt of tobacco_ and that he must have been smoking the same morning. The pilot's statement that he only had two cigarettes during the previous month will be completely discountenanced.

But the best chance for the police will come when the private moving-wing machine begins to make an appearance. Then will dawn the true constabulary millennium.

The moving-wing machine, as it has been shown, can almost hover and can fly comfortably at five or ten miles per hour. One day a moving-wing machine will pass through a police-trap while its pilot is admiring the countryside or inquiring from his companion where they will stop for lunch.

The pilot will appear in Court charged with flying at less than 40 miles per hour, and there will be a sensation when the detectives disclose that defendant's speed, which he did not deny, was 8 miles per hour over a measured furlong.

The magistrate will say that, although he had been on that bench for thirty-five years, never in his whole experience, never from the moment that he had accepted those duties, never since the time when he devoted himself to the administration of justice, _never_ had he heard of such a flagrant disregard for the safety of the public. Here was a flying-machine, over a populous area, travelling at 8 miles per hour when everyone knew that a flying-machine gained its lift by virtue of its speed through the air, and that if it travelled at less than forty miles per hour it was liable at any moment to fall upon the heads of the people below.

The pilot might endeavour to explain the technical points in the case. If he did so, his fine would be greater than if he merely pleaded guilty and said no more.

That case will be the signal for a wholesale persecution of moving-wing aircraft-owners. The Home Secretary will issue warnings, magistrates will wish that they could send pilots to prison—in fact there will be the usual process of departmental browbeating which we know so well. The theory that the private flyer will not be summoned for slow flying because there will be moving-wing passenger aircraft also capable of slow flying, does not bear investigation. There are now lorries, motor-buses, charabancs, steam-wagons, and trams which persistently exceed the 20-miles per hour speed limit. They are not prosecuted, nor will the passenger aircraft of the future be prosecuted.

Having given some idea of the delightful future which lies before the private flyer, I will add a few remarks upon air-racing.

After motor-road racing, air-racing is the finest sport yet invented. I give it ten more years life in England.

Before the War air-racing at Hendon was highly successful in that it attracted many entries and large crowds of spectators. Since the War air-racing has been unsuccessful. There are signs, however, that there will soon be a revival of it. Larger and larger crowds will collect to watch it. Special machines will be constructed, the number of entries will increase, continental firms will take part.

Then the statesman will step in and play his part, as he always must when anything becomes popular.

Air-racing is and will remain dangerous. Statesmen and newspapers will discover this and talk about it. Now I am informed upon the best authority that in England no one is allowed to face danger of any kind, whether he wants to or not. The State arranges that all dangers, physical and moral, are kept away from the individual. He may not do, see, hear smell, or taste anything calculated to arouse him from the suety state of mind so highly esteemed by the politician. The Englishman is nursed from birth to death by an army of officials. He is permitted to risk his life only in war.

Air-racing, since it is dangerous, will gradually be stamped out of existence. Air-racing improves the aircraft as a machine-entity; it would have a good effect upon the private flyer's machine and upon the war-machine. When air-racing has been stopped, therefore, a decline in the quality of the private flying-machine and the service-machine will result.

Air-racing (with which I include record-breaking) is as important to pure aeronautical development as anything else. The history of the Schneider Cup seaplane-race is some indication of the technical advance racing achieves. In 1913 at Monaco the Schnieder Cup, was won by France at 45.4 m.p.h. In 1914 (England) at 86.4 m.p.h., in 1919 (Italy) at 124.9 m.p.h. (This race was declared void). In 1920 (Italy) at 107.2 m.p.h. In 1921 (Italy) at 111.4 m.p.h., in 1922 (England) at 146.1 m.p.h., in 1923 (America) 177.4 m.p.h., in 1925 (America) 234.4 m.p.h. and in 1926 (Italy) at 246.5 m.p.h. (Fig. 3).

[Illustration: _Fig. 3 Schneider Cup_]

The Schneider Cup figures show that the much boasted rapidity of progress in the performance of high-speed aircraft during the War is a myth. During the War, progress was almost completely stopped. Even if the Italian win of 1919 at 124.9 m.p.h. be accepted (and the race was declared void because Janello was not observed at one of the turning-points) the rate of progress compares unfavourably with the rates before and after the War. If, on the other hand, the rate be judged by the accepted wins of 1914 and 1920 then the top speed of seaplanes rose only 20.8 m.p.h. in 6 years against 139.3 m.p.h. in 6 years after the War.

Up to 1926 there has been little sign of a falling off in the rate of progress in high-speed seaplane-design, and a rough estimate, puts the probable speed of the winner in 1928 at 290 m.p.h. and in 1930 at 320 m.p.h.

Record-breaking has a similar effect to racing upon technical development. In 1919 Sir John Alcock and Sir A. Whitten Brown flew the Atlantic non-stop for the first time in a heavier-than-air machine. They covered 1,890 miles in about 16 hours. In 1926 M. Dieudonné Coste and Capitaine Rignot covered 3,400 miles non-stop in 32 hours.

Whatever country takes up and encourages private flying, air-racing and record-breaking will play a big part in the future of the flying-machine.

VI

I see no reason to depart from the forecast of the future military flying-machine which I make in my _Strategy and Tactics of Air Fighting_.

Since the fixed-wing machine will probably retain a slightly superior performance over the moving-wing machine (although it is fair to Señor de la Cierva to add that some of the best mathematicians find on theoretical calculation that the moving-wing aircraft should be equal in all-round performance to the fixed-wing type), it is likely that, excepting a proportion of army co-operation machines and a small proportion of night-bombers the moving-wing machine will not in the future be used in large numbers for war purposes.

Before constructing the machine of the future, let us go to the R.A.F. annual Display, and refusing to be fascinated by the intricate shape of the breeches worn by officers and men, let us examine an experimental single-seater fighter of the present. When in the

air the machine is remarkable only for the undercarriage-struts and wheels which hang below the fuselage. They look like a labourer's hands in the drawing-room, they are sturdy but, in the air, they do not seem to know what to do with themselves, they are in unaccustomed surroundings.

Let this machine be compared with the gull. I use the gull for these comparisons because it is common and easily observed and so provides an accessible model. Indeed, it was the gull which instructed Mr A. V. Roe and helped him to become, on June 8th, 1908, the first man to fly over British soil. The experimental single-seater fighter at the R.A.F. Display has very few characteristics of which any bird need be ashamed. One of these characteristics, however, is undoubtedly its undercarriage. The gull folds up its undercarriage when it is in the air; it lets it down only when it is about to land.

But now compare the experimental machine with one of the standard machines in an R.A.F. squadron. The standard service-machine looks as if it has got into the hands of an accessory fiend, one of those who believe that the part is greater than the whole. It is so cluttered up with odds and ends, so cut about, modified, added to, and altered that it resembles no other flying-machine, animal or artificial. It is a sort of winged Air Ministry, a receptacle full of interesting information about everything but the air.

Since this mania for encumbering service-machines is only a superficial failing, it is possible, after remarking it, to go direct to the service-machine of the future.

There is first a new type to be noted, the aerial artillery-machine. This will be a large multi-engined monoplane carrying a single medium-sized gun and a few rounds of ammunition. It will be able to direct close range gunfire from the air at important ground-objectives. The advantage of the aerial big gun over the bomb will be in accuracy, the advantage of the bomb over the aerial big gun will be in the great weight of projectile made possible by the absence of any heavy launching-apparatus like a gun. The height of the aeroplane acts on the bomb as the explosive charge on the projectile. But at long ranges the bomb, with the newest sights and under the best conditions, is inaccurate, and at short ranges its velocity is low. The aerial big gun permits ground-objectives and ships to be attacked at short range with projectiles travelling at a high velocity.

The success of low-flying attacks by machine-guns in the late War was a sufficient demonstration of the potentialities of the low-altitude gun-attack from the air. Experiments were made long ago in mounting small guns in aeroplanes and in arranging for the absorption of the recoil. Against other aircraft the aerial big gun would not be used. In aerial fighting weight of projectile is of less importance than rate of fire.

The night-bombing machine of the future will be an immense flying-boat. It is likely that this type will also be used for day bombing. If so, it will be heavily armed with machine-guns and will not go out without a strong screen and escort of fighting machines.

The fighting aeroplane will be particularly interesting. It will be a small monoplane without external bracing-wires or struts and the undercarriage will be retractable. It will carry one man, and will be an all-metal machine mounting a gas-turbine of some 1,000 h.p.

Performance-figures must be the wildest guess work, because the closest examination of the trend of research gives but small information on the probable rates of progress in speed and climb. Mr A. V. Roe has frequently stated his belief that the future flying-machine will attain 1,000 miles per hour. I will, therefore, give my fighter of this generation 400 miles per hour, 800 miles per hour in the dive, a climb to 20,000 feet in 4 minutes, and a service-ceiling (the height at which the rate of climb falls below 100 feet per minute) of 60,000 feet.

In order that the fighter may operate at high altitudes, and in order that it may be able to change height suddenly by diving or climbing steeply, the pilot will be housed in a pressure-cockpit, from which he will look through a streamline conning-tower made in some transparent material. Unless he were enclosed in some such pressure-chamber or pressure-suit, the pilot would be unable to withstand the cold and the reduced pressure of extreme altitudes, and the sudden changes in temperature and pressure, when the machine was climbing or diving. Pressure-suits are now being experimented with in France and probably elsewhere.

Oxygen would be supplied to the pressure-chamber and an emergency oxygen-apparatus would provide against the chamber being pierced by a bullet. Some form of dessicating apparatus would be essential to prevent the transparent conning-tower from fogging up. The fewest accessories would be carried by these fighters of the future.

In general military aircraft will be more specialized than they are to-day, there will be no many-purpose machines. Instead, the number of specialist machines will steadily increase. In addition to the aerial big guns, there will be flying-tanks or lightly armoured

low-flying machines for attacks on ground-targets. These will be developed from the “Salamander”, “Vampire”, and other armoured aircraft introduced during the late War.

Armour for fighting and bombing-aircraft will not be employed for many years. The gunners on the large flying-boat bombers, however, will be provided with small shields.

Perhaps a general idea of the future of the flying-machine in war may best be given by quoting a newspaper report of a day air-attack on London in the next war.

I cut the headlines and start with Our Special Correspondent, who, with the printer’s assistance, has, if I may be permitted to say so, trodden on it through all four gears:

“The greatest air-raid in history was launched on London yesterday evening by a formation estimated at between six and seven hundred aeroplanes.

“For nearly two hours the earth shook to the thunder of the guns, while far up in the blue vault of Heaven there was the flash of wheeling wings, as the heroic pilots of the Royal Air Force plunged again and again to the attack.

“Never before has the heart of the Empire been the objective of so powerful and so determined an offensive, never before have the British air-forces so covered themselves with glory.

“Owing to the vigorous defence which met the raiders as they neared London, casualties are low. Official figures have not yet been issued, but it is thought that fewer than 1,000 people were killed while only some 7,000 were wounded.

“FIRST WARNING.

“The raiders were first reported by the ‘concrete ears’ or wireless disc and super-sensitive microphone sentries which encircle the coast. A large formation (there was much doubt as to the number of machines) was said to be approaching Southampton, and with the exception of three emergency squadrons, every R.A.F. fighting-aeroplane rushed to the attack.

“As our machines, sweeping through the freezing blue of the great altitudes, approached the raiders, the raiders turned and made off at full speed. Our machines bent on reaching the enemy, tore after them.

“It was at this moment that ominous news came through. A second hostile formation, far larger than the first, had been detected approaching the East coast south of Harwich.

“Nearly the whole of the defending airforce was far away: London’s bosom was bared to the attack.

“The new formation—first given as 400 machines but later corrected to 600—was in four great layers and flying at 170 miles per hour.

“The three emergency R.A.F. squadrons, numbering 54 machines of an old type with five or six experimental machines from Martlesham Heath and Farnborough, went up at once and hurled themselves at the vast enemy formation.

“THREE TO ONE ODDS.

“The second layer of the hostile formation, which consisted of about 150 long-distance fighters, engaged them. A furious battle ensued, while the remainder of the hostile fleet, aerial big guns, flying-boat bombers, and, at an extreme altitude, a further batch of long-distance fighters, continued on their way towards London.

“The old R.A.F. machines were literally butchered by the whip-lashes of lead which cracked and curled from the small-calibre stream-fire enemy guns. One of our machines had both its wings cut off and fell to the ground with such force that the airscrew-boss was buried 18 feet in the earth.

“Meanwhile wireless messages had reached the R.A.F. formation, which had been drawn off by the feint attack on Southampton. _They had turned and were tearing to the rescue at 350 miles per hour._

“The two big formations were in sight of each other when the enemy was about 20 miles south west of Chelmsford. At this time there was no active opposition to the invaders in the air. Anti-aircraft batteries, however, were blackening the sky with shells, and had succeeded in bringing down two enemy machines.

“There seemed now no hope that London would escape the full force of the attack. Already two ten-ton wireless-controlled flying-bombs had struck the city. Even so there was little panic. The gas-mask distribution had worked well, and no one was unprovided. The usual shelters were made full use of, but many people, against the orders of the police, remained in the streets anxiously looking skywards and listening to the almost continuous tear and roar of the guns.

“ANXIOUS MOMENTS.

“For some reason the news that the first hostile formation had retired had not come through on the wireless. And, since no one knew that far the greater part of the R.A.F. defending forces had gone in pursuit of that formation or that the emergency squadrons had been cut to pieces, a good deal of uneasiness prevailed among the watchers.

“Where are the R.A.F. fighters? was the question uppermost in everyone’s mind.

“As the noise of the guns grew louder and seemed to vibrate and echo among the houses, considerable alarm was displayed. There were one or two ugly scenes, and some women and children were trampled to death in raid shelters at Hoxton and Liverpool Street.

“A quarter of an hour before dusk the two lower layers of the hostile formation were sighted by some people who had been foolish enough to take up positions on the roof of the _Daily Post_ offices in Fleet Street. Only the trained eyes of the anti-aircraft spotters aided by the new visual detection instruments could distinguish the upper layers.

“Still there was no sign of our aeroplanes. The stories of those irresponsible alarmists who, in books and articles, have prophesied as far back as 1927 that London would be wiped out by aerial attack, seemed likely to prove too true. Excitement among the watchers gave way to a certain grimness. Then came a change in the situation.

“‘What’s that?’

“THE BATTLE JOINED.

“Someone was pointing immediately overhead. Nothing could at first be distinguished in the blue sky; then someone else waved excitedly.

“‘Yes, I caught a glimpse.’

“Just then the light of the setting sun glinted momentarily on some infinitesimal speck like a minute silver fish, rushing through the air at a great height. No one dared to express the hopes which they felt.

“A moment later what looked at first like a small red rose sprang into being high up over the enemy, high over the smoke-blackened sky where the anti-aircraft shells were bursting. Then it fell, like a flaming bomb. There was fighting going on up there, out of sight, in the upper air.

“Still the lower hostile layers came on through the roar and shock of the anti-aircraft fire. They were already over the outskirts of London. Something else fell from above twisting horribly. The white of parachutes drifting fantastically could be observed through high-powered glasses.

“Quite suddenly the continuous thunder of the anti-aircraft fire ceased. It was succeeded by an uncanny calm, and then by a high-pitched metallic scream which grew in an ear-piercing crescendo. _The R.A.F. aerial destroyers were engaging the lower enemy layers._

“The R.A.F. arrows of the upper air plunged into the very heart of the raiders, streaming fire and lead. They wheeled and turned among them with a swift, purposeful agility.

“RAIN OF BOMBS.

“The hostile formation began to split up, and simultaneously the enemy commander gave by wireless the order to bomb. On the outskirts of London huge factories and houses were suddenly transformed into pillars of white dust. The shriek and thump of the falling bombs was heard clearly in Central London.

“‘It was as if the ground were being torn up under your feet’, said a postman eyewitness. ‘The people in the shelters came out and began to run. They didn’t stop to think; they just ran like wild beasts, trampling on each other, and hitting out at anyone who got in the way, whether man, woman or child.

“‘The rain of bombs was so continuous that for as far as you could see earth and buildings were spouting up in the air with human limbs mixed up in them. The sound of the bombs falling was what knocked people’s nerves up as much as anything.

“‘The gas-bombs didn’t seem so bad, but the incendiary bombs were a nasty sight, at one time it looked as if the whole air had caught fire.’

“According to official information, damage was small. Only the aerial artillery-machines attained an objective of military importance. They completely destroyed the F.E. aircraft factory at Finsbury Park.

“The raiders had timed their attack so as to escape in the dark, and, although the new night detection flood-lights worked well, there is no doubt that the hostile casualties were so few because our fighters were hampered by the darkness.

“According to figures supplied by the Air Department of the War Ministry, 37 hostile machines were brought down while only eighteen of our own aerial destroyers were lost. The three emergency R.A.F. squadrons which first attacked lost 39 machines and had several more severely damaged.

“The raid is regarded by experts as a decisive victory for the British Air-arm and a complete and convincing justification of the policy of the Air-staff. It is pointed out that the raiders were prevented from reaching their objective, and that, apart from the old-type R.A.F. machines, our casualties are smaller than those of the enemy.”

In another part of the same paper was this insignificant paragraph.

“A late Central News message, delayed owing to the disorganization caused by yesterday’s air-raid, states that the hostile formation which made a feint attack on Southampton and was driven off by our machines, later returned to the same place and bombed it continuously for half an hour, causing many casualties and much material damage.”

In the stop-press news was this:

“One a.m. Large hostile formation of aircraft reported approaching mouth of Thames.”

In the above skit I have not dwelt on the terrible side of air-warfare in the future. Yet I feel that that is the side upon which all who are competent to do so, and who wish to prevent future wars should dwell. Several novels have given pictures of future aerial warfare, but I have not seen its inevitable horrors realistically portrayed. Unless those horrors are portrayed frequently and in their true and shocking form, people will soon forget the unpleasant side of air-war and think only of its romantic and glorious side.

In the interests of humanity it would be a good thing if some able novelist or film-producer would give us a statement of the crude horrors of air-war. If such a one arises, he will have the satisfaction of having helped the cause of peace and of having his work banned by the Censor.

VII

So far I have spoken only of heavier-than-air flying-machines. There is also the airship to which many people pin their faith for future long-distance air-transport.

The airship was neglected in England after the War because experience seemed to show that it was incapable of playing a useful part in warfare. Its revival was chiefly due to Commander Burney, who continually drew attention to his conviction that the airship could be made a safe and successful long-distance air-transport vehicle.

Most airship advocates believe in the bigger the better theory. If the gas-capacity of an airship is doubled, the disposable lift may be quadrupled, and the size will be only about 1.3 times that of the smaller vessel. For this reason the two English airships now being built are each of 5,000,000 cu. ft. gas-capacity. One is being built by the Government, the other for the Government to Commander Burney’s general design.

These airships have provided matter for many speeches on Empire air-ship-routes of the future. At the recent Imperial Conference airships were spoken of as the right vessels for long-distance air-lines. These forecasts are based on slender foundations.

Since 1914 only one successful commercial airship-service has been run. The ‘Bodensee’ in 1919 made 103 trips between Berlin and Friedrichshafen and carried 2450 passengers. Those 103 trips seem to be an insecure basis upon which to build calculations about voyages halfway round the world. The new airships may go from England to Egypt in 2½ days, and from England to Melbourne in 12½ days, but nothing has occurred in airship-development to strengthen the probability of such events. The two new airships are nothing more than a gigantic experiment.

I must make some unpleasant remarks about airships, but, before doing so, it is necessary to record admiration of the English airship policy. I do not agree with the man with a genius for mixed metaphor who described the airship scheme as the “thin edge of the white elephant”. On the contrary, in initiating this experiment the Government has shown imagination and daring. Airship enthusiasts are to have an opportunity of testing their theories. If the experiment is a hopeless failure no money and no time will have been wasted, for the knowledge gained will be of value in directing future aeronautical development.

But to the question: Will the airship become the long-distance air vehicle of the future? I answer No.

I base my view on an examination of airship history and on the opinions of airship pilots. Upon that basis the probable future of the 5,000,000 cu. ft. vessels will be this:

The first one to be completed will make a first flight, and come to its 200 ft. mooring mast successfully. For several months it will cruise periodically, and minor structural modifications will be made. It will fly to India and back. Paying passengers will be accepted, and after considerable delay the first long-distance passenger-flight will be flown. Some two or three years after the airship comes from its shed, it will meet with disaster.

More airships will be designed and built, larger still than those now building. There will be another disaster.

By then the heavier-than-air machine in the moving-wing and fixed-wing forms, will have proved itself capable of doing all that airships can do and doing it more safely, more quickly, more regularly, and more cheaply. The airship will gradually disappear, and its place will be taken by the heavier-than-air craft, as the balloon is gradually disappearing and its place being taken by the airship.

There is only one major difference between balloon and airship, a difference in the amount of control exercised by the airman. The same difference exists between airship and aeroplane. The aeroplane is the more controllable. It can rise and descend with less preliminary juggling; it can turn more quickly; and it can land more quickly.

In support of my pessimistic forecast I append a brief outline of air-ship-history.

Lighter-than-air man-carrying flight started in 1783 when Pilâtre de Rozier, the world’s first aeronaut, went up in a Montgolfier balloon. In the same year a hydrogen filled balloon flew from Paris to Nesle. In the following year an oblong balloon propelled by parasols as oars was made by the Duc de Chartres.

In 1852 a small airship propelled by a steam engine was made. In 1882 Tissandier’s airship worked by an electric motor was flown, and in 1884 the airship ‘La France’ was flown. Count Zeppelin built his first airship in 1900. Santos Dumont constructed an airship, and, in 1902, flew it round the Eiffel Tower.

It will be seen that the airship has passed through a longer period of development than the heavier-than-air flying-machine, even if the claim that Clement Ader flew in 1897 be accepted. Lighter-than-air flight, indeed, dates back to 1783.

The result of that longer development period is not such as to warrant too sanguine a belief in the airship’s future. The accidents to non-rigids and rigids have been many in proportion to the number of vessels actually flown.

The last type of non-rigid built in England was the North Sea type, one of which was destroyed by lightning soon after the War. Nine people were killed. Among the rigids, R.34, which made the double Atlantic crossing, was damaged beyond repair in 1921. R.33 has had many adventures, among them being her break-away from the mooring-mast in 1925. This was hailed as a proof of the safety of airships. R.33 is still alive, though she is treated with the respect due to her age.

R.36, the first British airship to be adapted for commercial purposes, is still in existence though not in service. R.38 broke up over the Humber in 1921 and forty-four people were killed.

The U.S.A. have the ‘Los Angeles’, which is the name now given to the German designed and built ZR.3. The ‘Shenandoah’ broke away from her mast in 1924, and was destroyed in 1926. According to survivors’ stories, the ‘Shenandoah’ was wrecked by the same kind of vertical air-currents that wrecked an early Zeppelin in 1913. In all, nine American airships have perished violently since the War.

The French ‘Dixmude’ was the ex-Zeppelin L.72. She created a world’s record in 1923, and then disappeared off Sicily with all hands (54 people).

Considering how few large airships have been built, and how short a time they are, on the average, kept in service, the proportion of serious accidents is high. In war that proportion is prohibitively high.

The Zeppelin works have turned out more rigid airships than any factory in the world. The fate of every Zeppelin airship completed since 1915 was recently given in a French technical paper. I do not vouch for the figures, but they come from a fairly reliable source. Out of 76 airships no fewer than 37 (or nearly 50%) were put out of service before they had completed one year’s work. Only four airships were kept in service for more than three years. This is the record of the firm which knows more about airships than any other firm in the world. Yet airships have had longer to develop than aeroplanes.

How can an airship be said to be superior to a fixed-wing aeroplane? It can hover, it has a longer range, it provides a higher degree of comfort for its passengers. How is it inferior to a fixed-wing aeroplane? It is slower, it requires more elaborate ground organization, it is less controllable. Since the moving-wing aircraft is, as yet, far from fully developed, I leave it out of discussion.

The argument that an aeroplane is always using a part of its power for lifting is counterbalanced by the argument that an airship is always using a part of its power for driving its bulk against the wind. An airship cannot stand still and use no power. There is always some wind at a height, and the airship must either use power or drift. An airship with all its engines stopped is as helpless as an aeroplane with all its engines stopped. The aeroplane, while gliding, still retains a large measure of controllability, and the pilot can select its landing ground within 50 yards. The airship has less controllability when its engines are stopped. Its commander would be lucky if he could select its landing ground within 50 miles.

It is right that the airship should have every chance to develop. If it prove successful, so much the better. I do not think it will prove successful. If it is made to work, it will be at more than ten times the cost in money and lives, at which heavier-than-air machines have been made to work.

Sometimes it seems regrettable that even a small part of the sums spent on developing airships cannot be spent on developing the passenger-carrying aeroplane.

I will give airships the last word by recalling that Sir George Cayley in 1816 expressed his belief that airships would eventually prove the most efficient and safest means of air travel, and by quoting Dr Eckener:

“A modern airship”, said Dr Eckener, “is at least as capable in heavy weather as a modern aeroplane. A storm will never have more effect than delaying or speeding a trip, and it can become directly dangerous only inasmuch as it may delay the voyage beyond the reach of fuel supply.”

VIII

“_Sans nul doute, l’avenir est a la bête de métal._” People regret the age of the machine: I cannot do so. A well-made machine, in which are struck into life the dreams of its designer, is a vital, individual creation.

A flying machine designed by a man with a sense of flight is more faithful and far more intelligent than a horse or a dog. Thoughts are reflected in it, the careful skill of the executant is expressed in its every component. It is sensitive and quick to feel roughness or gentleness in the hand of him who controls it. Its moods are without number, and it can surprise, please, and irritate. It is susceptible to being coaxed, and it enjoys obeying one whose orders are firmly given. But it can be treacherous to the weak or to one who does not try to understand it or who is persistently cruel to it.

At present there is a tendency to knock the life out of the machine, to subdue it to the level of tooth paste and tin cans. If that tendency makes headway, the flying-machine of the future must lose its individuality, and the age of the machine may eventually prove to be a dark age.

+——+ | | | _SIXTY VOLUMES ARE NOW PUBLISHED_ | | | | TO-DAY AND | | TO-MORROW | | | | _Each, pott 8vo, boards, 2/6 net_ | | | | | | This series of books, by some of the | | most distinguished English thinkers, | | scientists, philosophers, doctors, | | critics, and artists, was at once | | recognized as a noteworthy event. | | Written from various points of view, one | | book frequently opposing the argument | | of another, they provide the reader | | with a stimulating survey of the most | | modern thought in many departments of | | life. FROM THE REVIEWS

Times Literary Supplement: “An entertaining series of vivacious and stimulating studies of modern tendencies.”

Spectator: “Scintillating monographs ... that very lively and courageous series.”

Observer: “There seems no reason why the brilliant To-day and To-morrow Series should come to an end for a century of to-morrows. At first it seemed impossible for the publishers to keep up the sport through a dozen volumes, but the series already runs to more than two score. A remarkable series....”

Daily Telegraph: “This admirable series of essays, provocative and brilliant.”

Nation: “We are able to peer into the future by means of that brilliant series [which] will constitute a precious document upon the present time.”—_T. S. Eliot._

Manchester Dispatch: “The more one reads of these pamphlets, the more avid becomes the appetite. We hope the list is endless.”

Irish Statesman: “Full of lively controversy.”

Daily Herald: “This series has given us many monographs of brilliance and discernment.... The stylistic excellencies of this provocative series.”

Field: “We have long desired to express the deep admiration felt by every thinking scholar and worker at the present day for this series. We must pay tribute to the high standard of thought and expression they maintain. As small gift-books, austerely yet prettily produced, they remain unequalled of their kind. We can give but the briefest suggestions of their value to the student, the politician, and the voter....”

New York World: “Holds the palm in the speculative and interpretative thought of the age.”

VOLUMES READY

=Daedalus=, or Science and the Future. By J. B. S. HALDANE, Reader in Biochemistry, University of Cambridge. _Seventh impression._

“A fascinating and daring little book.”—_Westminster Gazette._ “The essay is brilliant, sparkling with wit and bristling with challenges.”—_British Medical Journal._ “Predicts the most startling changes.”—_Morning Post._

=Callinicus=, a Defence of Chemical Warfare. By J. B. S. HALDANE. _Second impression._

“Mr Haldane’s brilliant study.”—_Times Leading Article._ “A book to be read by every intelligent adult.”—_Spectator._ “This brilliant little monograph.”—_Daily News._

=Icarus=, or the Future of Science. By BERTRAND RUSSELL, F.R.S. _Fourth impression._

“Utter pessimism.”—_Observer._ “Mr Russell refuses to believe that the progress of Science must be a boon to mankind.”—_Morning Post._ “A stimulating book, that leaves one not at all discouraged.”—_Daily Herald._

=What I Believe.= By BERTRAND RUSSELL, F.R.S. _Third impression._

“One of the most brilliant and thought-stimulating little books I have read—a better book even than _Icarus_.”—_Nation._ “Simply and brilliantly written.”—_Nature._ “In stabbing sentences he punctures the bubble of cruelty, envy, narrowness, and ill-will which those in authority call their morals.”—_New Leader._

=Tantalus=, or the Future of Man. By F. C. S. SCHILLER, D.SC., Fellow of Corpus Christi College, Oxford. _Second impression._

“They are all (_Daedalus_, _Icarus_, and _Tantalus_) brilliantly clever, and they supplement or correct one another.”—_Dean Inge_, in _Morning Post_. “Immensely valuable and infinitely readable.”—_Daily News._ “The book of the week.”—_Spectator._

=Cassandra=, or the Future of the British Empire. By F. C. S. SCHILLER, D.SC.

“We commend it to the complacent of all parties.”—_Saturday Review._ “The book is small, but very, very weighty; brilliantly written, it ought to be read by all shades of politicians and students of politics.”—_Yorkshire Post._ “Yet another addition to that bright constellation of pamphlets.”—_Spectator._

=Quo Vadimus?= Glimpses of the Future. By E. E. FOURNIER D’ALBE, D.SC. _Second Impression._

“A wonderful vision of the future. A book that will be talked about.”—_Daily Graphic._ “A remarkable contribution to a remarkable series.”—_Manchester Dispatch._ “Interesting and singularly plausible.”—_Daily Telegraph._

=Thrasymachus=, the Future of Morals. By C. E. M. JOAD, author of “The Babbitt Warren,” etc. _Second impression._

“His provocative book.”—_Graphic._ “Written in a style of deliberate brilliance.”—_Times Literary Supplement._ “As outspoken and unequivocal a contribution as could well be imagined. Even those readers who dissent will be forced to recognize the admirable clarity with which he states his case. A book that will startle.”—_Daily Chronicle._

=Lysistrata=, or Woman’s Future and Future Woman. By ANTHONY M. LUDOVICI, author of “A Defence of Aristocracy,” etc. _Second Impression._

“A stimulating book. Volumes would be needed to deal, in the fullness his work provokes, with all the problems raised.”—_Sunday Times._ “Pro-feminine but anti-feministic.”—_Scotsman._ “Full of brilliant common-sense.”—_Observer._

=Hypatia=, or Woman and Knowledge. By MRS BERTRAND RUSSELL. With a frontispiece. _Third impression._

An answer to _Lysistrata_. “A passionate vindication of the rights of woman.”—_Manchester Guardian._ “Says a number of things that sensible women have been wanting publicly said for a long time.”—_Daily Herald._

=Hephaestus=, the Soul of the Machine. By E. E. FOURNIER D’ALBE, D.SC.

“A worthy contribution to this interesting series. A delightful and thought-provoking essay.”—_Birmingham Post._ “There is a special pleasure in meeting with a book like _Hephaestus_. The author has the merit of really understanding what he is talking about.”—_Engineering._ “An exceedingly clever defence of machinery.”—_Architects’ Journal._

=The Passing of the Phantoms=: a Study of Evolutionary Psychology and Morals. By C. J. PATTEN, Professor of Anatomy, Sheffield University. With 4 Plates.

“Readers of _Daedalus_, _Icarus_ and _Tantalus_, will be grateful for an excellent presentation of yet another point of view.”—_Yorkshire Post._ “This bright and bracing little book.”—_Literary Guide._ “Interesting and original.”—_Medical Times._

=The Mongol in our Midst=: a Study of Man and his Three Faces. By F. G. CROOKSHANK, M.D., F.R.C.P. With 28 Plates. _Second Edition, revised._

“A brilliant piece of speculative induction.”—_Saturday Review._ “An extremely interesting and suggestive book, which will reward careful reading.”—_Sunday Times._ “The pictures carry fearful conviction.”—_Daily Herald._

=The Conquest of Cancer.= By H. W. S. WRIGHT, M.S., F.R.C.S. Introduction by F. G. CROOKSHANK, M.D.

“Eminently suitable for general reading. The problem is fairly and lucidly presented. One merit of Mr Wright’s plan is that he tells people what, in his judgment, they can best do, _here and now_.”—From the _Introduction_.

=Pygmalion=, or the Doctor of the Future. By R. MCNAIR WILSON, M.B.

“Dr Wilson has added a brilliant essay to this series.”—_Times Literary Supplement._ “This is a very little book, but there is much wisdom in it.”—_Evening Standard._ “No doctor worth his salt would venture to say that Dr Wilson was wrong.”—_Daily Herald._

=Prometheus=, or Biology and the Advancement of Man. By H. S. JENNINGS, Professor of Zoology, Johns Hopkins University. _Second Impression._

“This volume is one of the most remarkable that has yet appeared in this series. Certainly the information it contains will be new to most educated laymen. It is essentially a discussion of ... heredity and environment, and it clearly establishes the fact that the current use of these terms has no scientific justification.”—_Times Literary Supplement._ “An exceedingly brilliant book.”—_New Leader._

=Narcissus=: an Anatomy of Clothes. By GERALD HEARD. With 19 illustrations.

“A most suggestive book.”—_Nation._ “Irresistible. Reading it is like a switchback journey. Starting from prehistoric times we rocket down the ages.”—_Daily News._ “Interesting, provocative, and entertaining.”—_Queen._

=Thamyris=, or Is There a Future for Poetry? By R. C. TREVELYAN.

“Learned, sensible, and very well-written.”—_Affable Hawk_, in _New Statesman_. “Very suggestive.”—_J. C. Squire_, in _Observer_. “A very charming piece of work, I agree with all, or at any rate, almost all its conclusions.”—_J. St Loe Strachey_, in _Spectator_.

=Proteus=, or the Future of Intelligence. By VERNON LEE, author of “Satan the Waster,” etc.

“We should like to follow the author’s suggestions as to the effect of intelligence on the future of Ethics, Aesthetics, and Manners. Her book is profoundly stimulating and should be read by everyone.”—_Outlook._ “A concise, suggestive piece of work.”—_Saturday Review._

=Timotheus=, the Future of the Theatre. By BONAMY DOBRÉE, author of “Restoration Drama,” etc.

“A witty, mischievous little book, to be read with delight.”—_Times Literary Supplement._ “This is a delightfully witty book.”—_Scotsman._ “In a subtly satirical vein he visualizes various kinds of theatres in 200 years’ time. His gay little book makes delightful reading.”—_Nation._

=Paris=, or the Future of War. By Captain B. H. LIDDELL HART.

“A companion volume to _Callinicus_. A gem of close thinking and deduction.”—_Observer._ “A noteworthy contribution to a problem of concern to every citizen in this country.”—_Daily Chronicle._ “There is some lively thinking about the future of war in Paris, just added to this set of live-wire pamphlets on big subjects.”—_Manchester Guardian._

=Wireless Possibilities.= By Professor A. M. LOW. With 4 diagrams.

“As might be expected from an inventor who is always so fresh, he has many interesting things to say.”—_Evening Standard._ “The mantle of Blake has fallen upon the physicists. To them we look for visions, and we find them in this book.”—_New Statesman._

=Perseus=: of Dragons. By H. F. SCOTT STOKES. With 2 illustrations.

“A diverting little book, chock-full of ideas, Mr Stokes’ dragon-lore is both quaint and various.”—_Morning Post._ “Very amusingly written, and a mine of curious knowledge for which the discerning reader will find many uses.”—_Glasgow Herald._

=Lycurgus=, or the Future of Law. By E. S. P. HAYNES, author of “Concerning Solicitors,” etc.

“An interesting and concisely written book.”—_Yorkshire Post._ “He roundly declares that English criminal law is a blend of barbaric violence, medieval prejudices and modern fallacies.... A humane and conscientious investigation.”—_T.P.’s Weekly._ “A thoughtful book—deserves careful reading.”—_Law Times._

=Euterpe=, or the Future of Art. By LIONEL R. MCCOLVIN, author of “The Theory of Book-Selection.”

“Discusses briefly, but very suggestively, the problem of the future of art in relation to the public.”—_Saturday Review._ “Another indictment of machinery as a soul-destroyer ... Mr McColvin has the courage to suggest solutions.”—_Westminster Gazette._ “This is altogether a much-needed book.”—_New Leader._

=Pegasus=, or Problems of Transport. By Colonel J. F. C. FULLER, author of “The Reformation of War,” etc. With 8 Plates.

“The foremost military prophet of the day propounds a solution for industrial and unemployment problems. It is a bold essay ... and calls for the attention of all concerned with imperial problems.”—_Daily Telegraph._ “Practical, timely, very interesting and very important.”—_J. St Loe Strachey_, in _Spectator_.

=Atlantis=, or America and the Future. By Colonel J. F. C. FULLER.

“Candid and caustic.”—_Observer._ “Many hard things have been said about America, but few quite so bitter and caustic as these.”—_Daily Sketch._ “He can conjure up possibilities of a new Atlantis.”—_Clarion._

=Midas=, or the United States and the Future. By C. H. BRETHERTON, author of “The Real Ireland,” etc.

A companion volume to _Atlantis_. “Full of astute observations and acute reflections ... this wise and witty pamphlet, a provocation to the thought that is creative.”—_Morning Post._ “A punch in every paragraph. One could hardly ask for more ‘meat.’”—_Spectator._

=Nuntius=, or Advertising and its Future. By GILBERT RUSSELL.

“Expresses the philosophy of advertising concisely and well.”—_Observer._ “It is doubtful if a more straightforward exposition of the part advertising plays in our public and private life has been written.”—_Manchester Guardian._

=Birth Control and the State=: a Plea and a Forecast. By C. P. BLACKER, M.C., M.A., M.R.C.S., L.R.C.P.

“A very careful summary.”—_Times Literary Supplement._ “A temperate and scholarly survey of the arguments for and against the encouragement of the practice of birth control.”—_Lancet._ “He writes lucidly, moderately, and from wide knowledge; his book undoubtedly gives a better understanding of the subject than any other brief account we know. It also suggests a policy.”—_Saturday Review._

=Ouroboros=, or the Mechanical Extension of Mankind. By GARET GARRETT.

“This brilliant and provoking little book.”—_Observer._ “A significant and thoughtful essay, calculated in parts to make our flesh creep.”—_Spectator._ “A brilliant writer, Mr Garrett is a remarkable man. He explains something of the enormous change the machine has made in life.”—_Daily Express._

=Artifex=, or the Future of Craftsmanship. By JOHN GLOAG, author of “Time, Taste, and Furniture.”

“An able and interesting summary of the history of craftsmanship in the past, a direct criticism of the present, and at the end his hopes for the future. Mr Gloag’s real contribution to the future of craftsmanship is his discussion of the uses of machinery.”—_Times Literary Supplement._

=Plato’s American Republic.= By J. DOUGLAS WOODRUFF. _Fourth impression._

“Uses the form of the Socratic dialogue with devastating success. A gently malicious wit sparkles in every page.”—_Sunday Times._ “Having deliberately set himself an almost impossible task, has succeeded beyond belief.”—_Saturday Review._ “Quite the liveliest even of this spirited series.”—_Observer._

=Orpheus=, or the Music of the Future. By W. J. TURNER, author of “Music and Life.” _Second impression._

“A book on music that we can read not merely once, but twice or thrice. Mr Turner has given us some of the finest thinking upon Beethoven that I have ever met with.”—_Ernest Newman_ in _Sunday Times_. “A brilliant essay in contemporary philosophy.”—_Outlook._ “The fruit of real knowledge and understanding.”—_New Statesman._

=Terpander=, or Music and the Future. By E. J. DENT, author of “Mozart’s Operas.”

“In _Orpheus_ Mr Turner made a brilliant voyage in search of first principles. Mr Dent’s book is a skilful review of the development of music. It is the most succinct and stimulating essay on music I have found....”—_Musical News._ “Remarkably able and stimulating.”—_Times Literary Supplement._ “There is hardly another critic alive who could sum up contemporary tendencies so neatly.”—_Spectator._

=Sibylla=, or the Revival of Prophecy. By C. A. MACE, University of St. Andrew’s.

“An entertaining and instructive pamphlet.”—_Morning Post._ “Places a nightmare before us very ably and wittily.”—_Spectator._ “Passages in it are excellent satire, but on the whole Mr Mace’s speculations may be taken as a trustworthy guide ... to modern scientific thought.”—_Birmingham Post._

=Lucullus=, or the Food of the Future. By OLGA HARTLEY and MRS C. F. LEYEL, authors of “The Gentle Art of Cookery.”

“This is a clever and witty little volume in an entertaining series, and it makes enchanting reading.”—_Times Literary Supplement._ “Opens with a brilliant picture of modern man, living in a vacuum-cleaned, steam-heated, credit-furnished suburban mansion ‘with a wolf in the basement’—the wolf of hunger. This banquet of epigrams.”—_Spectator._

=Procrustes=, or the Future of English Education. By M. ALDERTON PINK.

“Undoubtedly he makes out a very good case.”—_Daily Herald._ “This interesting addition to the series.”—_Times Educational Supplement._ “Intends to be challenging and succeeds in being so. All fit readers will find it stimulating.”—_Northern Echo._

=The Future of Futurism.= By JOHN RODKER.

“Mr Rodker is up-to-the-minute, and he has accomplished a considerable feat in writing on such a vague subject, 92 extremely interesting pages.”—_T. S. Eliot_, in _Nation_. “There are a good many things in this book which are of interest.”—_Times Literary Supplement._

=Pomona=, or the Future of English. By BASIL DE SÉLINCOURT, author of “The English Secret”, etc.

“The future of English is discussed fully and with fascinating interest.”—_Morning Post._ “Full of wise thoughts and happy words.”—_Times Literary Supplement._ “His later pages must stir the blood of any man who loves his country and her poetry.”—_J. C. Squire_, in _Observer_. “His finely-conceived essay.”—_Manchester Guardian._

=Balbus=, or the Future of Architecture. By CHRISTIAN BARMAN.

“A really brilliant addition to this already distinguished series. The reading of _Balbus_ will give much data for intelligent prophecy, and incidentally, an hour or so of excellent entertainment.”—_Spectator._ “Most readable and reasonable. We can recommend it warmly.”—_New Statesman._ “This intriguing little book.”—_Connoisseur._

=Apella=, or the Future of the Jews. By A QUARTERLY REVIEWER.

“Cogent, because of brevity and a magnificent prose style, this book wins our quiet praise. It is a fine pamphlet, adding to the value of the series, and should not be missed.”—_Spectator._ “A notable addition to this excellent series. His arguments are a provocation to fruitful thinking.”—_Morning Post._

=The Dance of Çiva=, or Life’s Unity and Rhythm. By COLLUM.

“It has substance and thought in it. The author is very much alive and responsive to the movements of to-day.”—_Spectator._ “A very interesting account of the work of Sir Jagadis Bose.”—_Oxford Magazine._ “Has caught the spirit of the Eastern conception of world movements.”—_Calcutta Statesman._

=Lars Porsena=, or the Future of Swearing and Improper Language. By ROBERT GRAVES. _Third impression._

“Goes uncommonly well, and deserves to.”—_Observer._ “Not for squeamish readers.”—_Spectator._ “No more amusingly unexpected contribution has been made to this series. A deliciously ironical affair.”—_Bystander._ “His highly entertaining essay is as full as the current standard of printers and police will allow.”—_New Statesman._ “Humour and style are beyond criticism.”—_Irish Statesman._

=Socrates=, or the Emancipation of Mankind. By H. F. CARLILL.

“Devotes a specially lively section to the herd instinct.”—_Times._ “Clearly, and with a balance that is almost Aristotelian, he reveals what modern psychology is going to accomplish.”—_New Statesman._ “One of the most brilliant and important of a remarkable series.”—_Westminster Gazette._

=Delphos=, or the Future of International Language. By E. SYLVIA PANKHURST.

“Equal to anything yet produced in this brilliant series. Miss Pankhurst states very clearly what all thinking people must soon come to believe, that an international language would be one of the greatest assets of civilization.”—_Spectator._ “A most readable book, full of enthusiasm, an important contribution to this subject.”—_International Language._

=Gallio=, or the Tyranny of Science. By J. W. N. SULLIVAN, author of “A History of Mathematics.”

“So packed with ideas that it is not possible to give any adequate _résumé_ of its contents.”—_Times Literary Supplement._ “His remarkable monograph, his devastating summary of materialism, this pocket _Novum Organum_.”—_Spectator._ “Possesses a real distinction of thought and manner. It must be read.”—_New Statesman._

=Apollonius=, or the Future of Psychical Research. By E. N. BENNETT, author of “Problems of Village Life,” etc.

“A sane, temperate and suggestive survey of a field of inquiry which is slowly but surely pushing to the front.”—_Times Literary Supplement._ “His exposition of the case for psychic research is lucid and interesting.”—_Scotsman._ “Displays the right temper, admirably conceived, skilfully executed.”—_Liverpool Post._

=Aeolus=, or the Future of the Flying Machine. By OLIVER STEWART.

“Both his wit and his expertness save him from the nonsensical-fantastic. There is nothing vague or sloppy in these imaginative forecasts.”—_Daily News._ “He is to be congratulated. His book is small, but it is so delightfully funny that it is well worth the price, and there really are sensible ideas behind the jesting.”—_Aeroplane._

=Stentor=, or the Press of To-Day and To-Morrow. By DAVID OCKHAM.

“A valuable and exceedingly interesting commentary on a vital phase of modern development.”—_Daily Herald._ “Vigorous and well-written, eminently readable.”—_Yorkshire Post._ “He has said what one expects any sensible person to say about the ‘trustification’ of the Press.”—_Spectator._

=Rusticus=, or the Future of the Countryside. By MARTIN S. BRIGGS, F.R.I.B.A.

“Few of the 50 volumes, provocative and brilliant as most of them have been, capture our imagination as does this one.”—_Daily Telegraph._ “The historical part is as brilliant a piece of packed writing as could be desired.”—_Daily Herald._ “Serves a national end. The book is in essence a pamphlet, though it has the form and charm of a book.”—_Spectator._

=Janus=, or the Conquest of War. By WILLIAM MCDOUGALL, M.B., F.R.S.

“Among all the booklets of this brilliant series, none, I think is so weighty and impressive as this. It contains thrice as much matter as the other volumes and is profoundly serious.”—_Dean Inge_, in _Evening Standard_. “A deeply interesting and fair-minded study of the causes of war and the possibilities of their prevention. Every word is sound.”—_Spectator._

=Vulcan=, or the Future of Labour. By CECIL CHISHOLM.

“Of absorbing interest.”—_Daily Herald._ “No one, perhaps, has ever condensed so many hard facts into the appearance of agreeable fiction, nor held the balance so nicely between technicalities and flights of fancy, as the author of this excellent book in a brilliant series. _Vulcan_ is a little book, but between its covers knowledge and vision are pressed down and brimming over.”—_Spectator._

=Hymen=, or the Future of Marriage. By NORMAN HAIRE.

This candid and unprejudiced survey inquires why the majority of marriages to-day seem to be so unsatisfactory, and finds the answer in the sexual ethic of our civilization which is ill adapted to our social and economic needs. The problems of sex-morality, sex-education, prostitution, in-breeding, birth-control, trial-marriage, and polygamy are all touched upon.

=The Next Chapter=: the War against the Moon. By ANDRÉ MAUROIS, author of ‘Ariel’, etc.

This imaginary chapter of world-history (1951–64) from the pen of one of the most brilliant living French authors mixes satire and fancy in just proportions. It tells how the press of the world is controlled by five men, how world interest is focussed on an attack on the moon, how thus the threat of world-war is averted. But when the moon retaliates....

=Galatea=, or the Future of Darwinism. By W. RUSSELL BRAIN.

This non-technical but closely-reasoned book is a challenge to the orthodox teaching on evolution known as Neo-Darwinism. The author claims that, although Neo-Darwinian theories can possibly account for the evolution of forms, they are quite inadequate to explain the evolution of functions.

=Scheherazade=, or the Future of the English Novel. By JOHN CARRUTHERS.

A survey of contemporary fiction in England and America lends to the conclusion that the literary and scientific influences of the last fifty years have combined to make the novel of to-day predominantly analytic. It has thus gained in psychological subtlety, but lost its form. How this may be regained is put forward in the conclusion.

=Caledonia=, or the Future of the Scots. By G. M. THOMSON.

Exit the Scot! Under this heading the Scottish people are revealed as a leaderless mob in whom national pride has been strangled. They regard, unmoved, the spectacle of their monstrous slum-evil, the decay of their industries, the devastation of their countryside. This is the most compact and mordant indictment of Scottish policy that has yet been written.

=Albyn=, or Scotland and the Future. By C. M. GRIEVE, author of ‘Contemporary Scottish Studies’, etc.

A vigorous answer, explicit and implicit, to _Caledonia_, tracing the movements of a real Scottish revival, in music, art, literature, and politics, and coming to the conclusion that there is a chance even now for the regeneration of the Scottish people.

=Lares et Penates=, or the Future of the Home. By H. J. BIRNSTINGL.

All the many forces at work to-day are influencing the planning, appearance, and equipment of the home. This is the main thesis of this stimulating volume, which considers also the labour-saving movement, the ‘ideal’ house, the influence of women, the servant problem, and the relegation of aesthetic considerations to the background. Disconcerting prognostications follow.

NEARLY READY

=Archon=, or the Future of Government. By HAMILTON FYFE.

A survey of the methods of government in the past leads the author to a consideration of conditions in the world of to-day. He then indicates the lines along which progress may develop.

=Hermes=, or the Future of Chemistry. By T. W. JONES, B.SC., F.C.S.

Chemistry as the means of human emancipation is the subject of this book. To-day chemistry is one of the master factors of our existence; to-morrow it will dominate every phase of life, winning for man the goal of all his endeavour, economic freedom. It may also effect a startling change in man himself.

=The Future of Physics.= By L. L. WHYTE.

The last few years have been a critical period in the development of physics. We stand on the eve of a new epoch. Physics, biology, and psychology are converging towards a scientific synthesis of unprecedented importance whose influence on thought and social custom will be so profound as to mark a stage in human evolution. This book interprets these events and should be read in connexion with _Gallio_, by J. W. N. Sullivan, in this series.

=Ikonoclastes=, or the Future of Shakespeare. By HUBERT GRIFFITHS.

Taking as text the recent productions of classical plays in modern dress, the author, a distinguished dramatic critic, suggests that this is the proper way of reviving Shakespeare and other great dramatists of the past, and that their successful revival in modern dress may perhaps be taken as an indication of their value.

IN PREPARATION

=Bacchus=, or the Future of Wine. By P. MORTON SHAND.

=Mercurius=, or the World on Wings. By C. THOMPSON WALKER.

=The Future of Sport.= By G. S. SANDILANDS.

=The Future of India.= By T. EARLE WELBY.

=The Future of Films.= By ERNEST BETTS.

Transcriber's Note (continued)

Errors in punctuation and simple typos have been corrected without note. Archaic or variant spelling, inconsistent hyphenation, etc., has been left as it appears in the original publication unless as noted in the following:

Page 12 – "insistance" changed to "insistence" (The continued insistence that speed)

Page 35 – "persistance" changed to "persistence" (foretold with tiresome persistence)

End matter page 17 – "montrous" changed to "monstrous" (their monstrous slum-evil)

THE ORGANISATION OF THOUGHT

THE ORGANISATION OF THOUGHT

EDUCATIONAL AND SCIENTIFIC

BY A. N. WHITEHEAD, Sc.D., F.R.S.

FELLOW OF TRINITY COLLEGE, CAMBRIDGE, AND PROFESSOR OF APPLIED MATHEMATICS AT THE IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY

LONDON WILLIAMS AND NORGATE 14 HENRIETTA STREET, COVENT GARDEN, W.C.2 1917

The rights of translation are reserved

PREFACE

THE discourses included in this volume have been delivered as addresses on various occasions which are duly noted; the only exception is _The Anatomy of Some Scientific Ideas_, which is now published for the first time. These discourses fall into two sections, the first five chapters deal with education, and the remaining three embody discussions on certain points arising in the philosophy of science. But a common line of reflection extends through the whole, and the two sections influence each other.

I have left in each chapter the reference to the particular occasion of its first production, and I have not sought for a verbal consistency covering perplexity. But the various parts of the book were in fact composed with express reference to each other, so as to form one whole.

I have to thank the Syndics of the Cambridge University Press for permission to republish the contents of Chapter V.

Imperial College of Science and Technology, _April 1917._

TABLE OF CONTENTS

CHAP. PAGE

PREFACE v

I. THE AIMS OF EDUCATION--A PLEA FOR REFORM 1 (Presidential Address to the Mathematical Association, January, 1916.)

II. TECHNICAL EDUCATION AND ITS RELATION TO SCIENCE AND LITERATURE 29 (Presidential Address to the Mathematical Association, January, 1917.)

III. A POLYTECHNIC IN WAR-TIME 58 (Address at the Prize Distribution, Borough Polytechnic Institute, Southwark, February, 1917.)

IV. THE MATHEMATICAL CURRICULUM 69 (Presidential Address to the London Branch of the Mathematical Association, 1912.)

V. THE PRINCIPLES OF MATHEMATICS IN RELATION TO ELEMENTARY TEACHING 92 (Paper read in the Educational Section of the International Congress of Mathematicians, Cambridge, 1912.)

VI. THE ORGANISATION OF THOUGHT 105 (Presidential Address to Section A, British Association, Newcastle, 1916; also read subsequently before the Aristotelian Society.)

VII. THE ANATOMY OF SOME SCIENTIFIC IDEAS 134

VIII. SPACE, TIME, AND RELATIVITY 191 (Paper read to Section A at the Manchester Meeting of Section A, 1915; also, with the appended Commentary, read subsequently before the Aristotelian Society.)

ORGANISATION OF THOUGHT

CHAPTER I

THE AIMS OF EDUCATION--A PLEA FOR REFORM

(_Presidential Address to the Mathematical Association, January, 1916_)

WHEN I had the honour of being made President of the Mathematical Association, I did not foresee the unusual responsibility which it entailed. It was my intention to take as the theme of a presidential address the consideration of some aspect of those special subjects to which my own researches have principally been directed. Events have forced me to abandon that intention. It is useless to discuss abstract questions in the midst of dominant practical preoccupation. We cannot disregard the present crisis in European civilisation. It affects every function of life. In the harder struggle for existence which lies before the nation, all departments of national effort will be reviewed for judgment. The mere necessity for economy in resources will provoke this reformation.

We are concerned with education. This Association, so rich in its membership of educationalists, with the conception of reform as the very reason of its being, is among those bodies which must take the lead in guiding that educational reconstruction which by a sociological law follows every social revolution. We do not want impracticable ideals, only to be realised beyond the clouds in

"Some wild, weird clime, Out of Space, and out of Time."

We require to know what is possible now in England, a nation conscious of its high achievements, and of great failures, shaken to its foundations, distrustful of the old ways, and dreading fantastic novelties.

I will take my courage in both hands, and put before you an outline of educational principles. What I am going to say is of course entirely without your authority, and does not pledge or prejudge any action of the Association. We are primarily concerned only with the intellectual side of education, and, as mathematicians, are naturally concerned to illustrate details more particularly by reference to mathematics. Thus much to explain deliberate omissions in what follows.

Consider now the general and special education of two types of boys, namely those in secondary schools who in after life must form the professional and directing classes in commerce, industry, and public administration, and again those in junior technical schools and later in advanced continuation classes, who are going to form the class of skilled artisans and foremen of workshops. These two sets compose the educated strength of the nation. We must form no ideals which include less than these entire classes within their scope. What I shall say, will in phraseology apply more directly to the secondary schools, but with unessential changes it will apply equally to the other group.

What is the first commandment to be obeyed in any educational scheme? It is this: Do not teach too many subjects. The second command is this: What you teach, teach thoroughly. The devil in the scholastic world has assumed the form of a general education consisting of scraps of a large number of disconnected subjects; and, with the artfulness of the serpent, he has entrenched himself behind the matriculation examination of the University of London, with a wire entanglement formed by the Oxford and Cambridge schools' examination.

Culture is activity of thought, and receptiveness to beauty, and humane feeling. Scraps of information have nothing to do with it. A merely well-informed man is the most useless bore on God's earth. What we should aim at producing is men who possess both culture and expert knowledge in some special direction. Their expert knowledge will give them the ground to start from, and their culture will lead them as deep as philosophy and as high as art. We have to remember that the valuable intellectual development is self-development, and that it mostly takes place between the ages of sixteen and thirty. As to training, the most important part is given by mothers before the age of twelve. A saying due to Archbishop Temple illustrates my meaning. Surprise was expressed at the success in after-life of a man, who as a boy at Rugby had been somewhat undistinguished. He answered, "It is not what they are at eighteen, it is what they become afterwards that matters."

In training a child to activity of thought, above all things we must beware of what I will call "inert ideas"--that is to say, ideas that are merely received into the mind without being utilised, or tested, or thrown into fresh combinations.

In the history of education, the most striking phenomenon is that schools of learning, which at one epoch are alive with a ferment of genius, in a succeeding generation exhibit merely pedantry and routine. The reason is, that they are overladen with inert ideas. Education with inert ideas is not only useless: it is, above all things, harmful--_Corruptio optimi, pessima_. Except at rare intervals of intellectual ferment, education in the past has been radically infected with inert ideas. That is the reason why uneducated clever women, who have seen much of the world, are in middle life so much the most cultured part of the community. They have been saved from this horrible burden of inert ideas. Every intellectual revolution which has ever stirred humanity into greatness has been a passionate protest against inert ideas. Then, alas, with pathetic ignorance of human psychology, it has proceeded by some educational scheme to bind humanity afresh with inert ideas of its own fashioning.

Let us now ask how in our system of education we are to guard against this mental dry rot. We recur to our two educational commandments, "Do not teach too many subjects," and again, "What you teach, teach thoroughly."

The result of teaching small parts of a large number of subjects is the passive reception of disconnected ideas, not illumined with any spark of vitality. Let the main ideas which are introduced into a child's education be few and important, and let them be thrown into every combination possible. The child should make them his own, and should understand their application here and now in the circumstances of his actual life. From the very beginning of his education, the child should experience the joy of discovery. The discovery which he has to make, is that general ideas give an understanding of that stream of events which pours through his life, which is his life. By understanding I mean more than a mere logical analysis, though that is included. I mean "understanding" in the sense in which it is used in the French proverb, "To understand all, is to forgive all." Pedants sneer at an education which is useful. But if education is not useful, what is it? Is it a talent, to be hidden away in a napkin? Of course, education should be useful, whatever your aim in life. It was useful to Saint Augustine and it was useful to Napoleon. It is useful, because understanding is useful.

I pass lightly over that understanding which should be given by the literary side of education. It is not peculiarly the function of this Association to consider it. Nor do I wish to be supposed to pronounce on the relative merits of a classical or a modern curriculum. I would only remark that the understanding which we want is an understanding of an insistent present. The only use of a knowledge of the past is to equip us for the present. No more deadly harm can be done to young minds than by depreciation of the present. The present contains all that there is. It is holy ground; for it is the past, and it is the future. At the same time it must be observed that an age is no less past if it existed two hundred years ago than if it existed two thousand years ago. Do not be deceived by the pedantry of dates. The ages of Shakespeare and of Molière are no less past than are the ages of Sophocles and of Virgil. The communion of saints is a great and inspiring assemblage, but it has only one possible hall of meeting, and that is, the present; and the mere lapse of time through which any particular group of saints must travel to reach that meeting-place, makes very little difference.

Passing now to the scientific and logical side of education, we remember that here also ideas which are not utilised are positively harmful. By utilising an idea, I mean relating it to that stream, compounded of sense perceptions, feelings, hopes, desires, and of mental activities relating thought to thought, which forms our life. I can imagine a set of beings which might fortify their souls by passively reviewing disconnected ideas. Humanity is not built that way--except perhaps some editors of newspapers.

In scientific training, the first thing to do with an idea is to prove it. But allow me for one moment to extend the meaning of "prove"; I mean--to prove its worth. Now an idea is not worth much unless the propositions in which it is embodied are true. Accordingly an essential part of the proof of an idea is the proof, either by experiment or by logic, of the truth of the propositions. But it is not essential that this proof of the truth should constitute the first introduction to the idea. After all, its assertion by the authority of respectable teachers is sufficient evidence to begin with. In our first contact with a set of propositions, we commence by appreciating their importance. That is what we all do in after-life. We do not attempt, in the strict sense, to prove or to disprove anything, unless its importance makes it worthy of that honour. These two processes of proof, in the narrow sense, and of appreciation do not require a rigid separation in time. Both can be proceeded with nearly concurrently. But in so far as either process must have the priority, it should be that of appreciation by use.

Furthermore, we should not endeavour to use propositions in isolation. Emphatically I do not mean, a neat little set of experiments to illustrate Proposition I and then the proof of Proposition I, a neat little set of experiments to illustrate Proposition II and then the

proof of Proposition II, and so on to the end of the book. Nothing could be more boring. Inter-related truths are utilised _en bloc_, and the various propositions are employed in any order, and with any reiteration. Choose some important applications of your theoretical subject; and study them concurrently with the systematic theoretical exposition. Keep the theoretical exposition short and simple, but let it be strict and rigid so far as it goes. It should not be too long for it easily to be known with thoroughness and accuracy. The consequences of a plethora of half-digested theoretical knowledge are deplorable. Also the theory should not be muddled up with the practice. The child should have no doubt when it is proving and when it is utilising. My point is that what is proved should be utilised, and that what is utilised should--so far as is practicable--be proved. I am far from asserting that proof and utilisation are the same thing.

At this point of my discourse, I can most directly carry forward my argument in the outward form of a digression. We are only just realising that the art and science of education require a genius and a study of their own; and that this genius and this science are more than a bare knowledge of some branch of science or of literature. This truth was partially perceived in the past generation; and headmasters, somewhat crudely, were apt to supersede learning in their colleagues by requiring left-hand bowling and a taste for football. But culture is more than cricket, and more than football, and more than extent of knowledge.

Education is the acquisition of the art of the utilisation of knowledge. This is an art very difficult to impart. Whenever a text-book is written of real educational worth, you may be quite certain that some reviewer will say that it will be difficult to teach from it. Of course it will be difficult to teach from it. If it were easy, the book ought to be burned; for it cannot be educational. In education, as elsewhere, the broad primrose path leads to a nasty place. This evil path is represented by a book or a set of lectures which will practically enable the student to learn by heart all the questions likely to be asked at the next external examination. And I may say in passing that no educational system is possible unless every question directly asked of a pupil at any examination is either framed or modified by the actual teacher of that pupil in that subject. The external assessor may report on the curriculum or on the performance of the pupils, but never should be allowed to ask the pupil a question which has not been strictly supervised by the actual teacher, or at least inspired by a long conference with him. There are a few exceptions to this rule, but they are exceptions, and could easily be allowed for under the general rule.

We now return to my previous point, that theoretical ideas should always find important applications within the pupil's curriculum. This is not an easy doctrine to apply, but a very hard one. It contains within itself the problem of keeping knowledge alive, of preventing it from becoming inert, which is the central problem of all education.

The best procedure will depend on several factors, none of which can be neglected, namely, the genius of the teacher, the intellectual type of the pupils, their prospects in life, the opportunities offered by the immediate surroundings of the school, and allied factors of this sort. It is for this reason that the uniform external examination is so deadly. We do not denounce it because we are cranks, and like denouncing established things. We are not so childish. Also, of course, such examinations have their use in testing slackness. Our reason of dislike is very definite and very practical. It kills the best part of culture. When you analyse in the light of experience the central task of education, you find that its successful accomplishment depends on a delicate adjustment of many variable factors. The reason is that we are dealing with human minds, and not with dead matter. The evocation of curiosity, of judgment, of the power of mastering a complicated tangle of circumstances, the use of theory in giving foresight in special cases--all these powers are not to be imparted by a set rule embodied in one schedule of examination subjects.

I appeal to you, as practical teachers. With good discipline, it is always possible to pump into the minds of a class a certain quantity of inert knowledge. You take a text-book and make them learn it. So far, so good. The child then knows how to solve a quadratic equation. But what is the point of teaching a child to solve a quadratic equation? There is a traditional answer to this question. It runs thus: The mind is an instrument, you first sharpen it, and then use it; the acquisition of the power of solving a quadratic equation is part of the process of sharpening the mind. Now there is just enough truth in this answer to have made it live through the ages. But for all its half-truth, it embodies a radical error which bids fair to stifle the genius of the modern world. I do not know who was first responsible for this analogy of the mind to a dead instrument. For aught I know, it may have been one of the seven wise men of Greece, or a committee of the whole lot of them. Whoever was the originator, there can be no doubt of the authority which it has acquired by the continuous approval which it has received from eminent persons. But whatever its weight of authority, whatever the high approval which it can quote, I have no hesitation in denouncing it as one of the most fatal, erroneous, and dangerous conceptions ever introduced into the theory of education. The mind is never passive; it is a perpetual activity, delicate, receptive, responsive to stimulus. You cannot postpone its life until you have sharpened it. Whatever interest attaches to your subject-matter, must be evoked here and now; whatever powers you are strengthening in the pupil, must be exercised here and now; whatever possibilities of mental life your teaching should impart, must be exhibited here and now. That is the golden rule of

education, and a very difficult rule to follow.

The difficulty is just this: the apprehension of general ideas, intellectual habits of mind, and pleasurable interest in mental achievement can be evoked by no form of words, however accurately adjusted. All practical teachers know that education is a patient process of the mastery of details, minute by minute, hour by hour, day by day. There is no royal road to learning through an airy path of brilliant generalisations. There is a proverb about the difficulty of seeing the wood because of the trees. That difficulty is exactly the point which I am enforcing. The problem of education is to make the pupil see the wood by means of the trees.

The solution which I am urging, is to eradicate the fatal disconnection of subjects which kills the vitality of our modern curriculum. There is only one subject-matter for education, and that is Life in all its manifestations. Instead of this single unity, we offer children--Algebra, from which nothing follows; Geometry, from which nothing follows; Science, from which nothing follows; History, from which nothing follows; a Couple of Languages, never mastered; and lastly, most dreary of all, Literature, represented by plays of Shakespeare, with philological notes and short analyses of plot and character to be in substance committed to memory. Can such a list be said to represent Life, as it is known in the midst of the living of it? The best that can be said of it is, that it is a rapid table of contents which a deity might run over in his mind while he was thinking of creating a world, and had not yet determined how to put it together.

Let us now return to quadratic equations. We still have on hand the unanswered question. Why should children be taught their solution? Unless quadratic equations fit into a connected curriculum, of course there is no reason to teach anything about them. Furthermore, extensive as should be the place of mathematics in a complete culture, I am a little doubtful whether for many types of boys algebraic solutions of quadratic equations do not lie on the specialist side of mathematics. I may here remind you that as yet I have not said anything of the psychology or the content of the specialism, which is so necessary a part of an ideal education. But all that is an evasion of our real question, and I merely state it in order to avoid being misunderstood in my answer.

Quadratic equations are part of algebra, and algebra is the intellectual instrument which has been created for rendering clear the quantitative aspects of the world. There is no getting out of it. Through and through the world is infected with quantity. To talk sense, is to talk in quantities. It is no use saying that the nation is large,--How large? It is no use saying that radium is scarce,--How scarce? You cannot evade quantity. You may fly to poetry and to music, and quantity and number will face you in your rhythms and your octaves. Elegant intellects which despise the theory of quantity, are but half developed. They are more to be pitied than blamed. The scraps of gibberish, which in their school-days were taught to them in the name of algebra, deserve some contempt.

This question of the degeneration of algebra into gibberish, both in word and in fact, affords a pathetic instance of the uselessness of reforming educational schedules without a clear conception of the attributes which you wish to evoke in the living minds of the children. A few years ago there was an outcry that school algebra was in need of reform, but there was a general agreement that graphs would put everything right. So all sorts of things were extruded, and graphs were introduced. So far as I can see, with no sort of idea behind them, but just graphs. Now every examination paper has one or two questions on graphs. Personally, I am an enthusiastic adherent of graphs. But I wonder whether as yet we have gained very much. You cannot put life into any schedule of general education unless you succeed in exhibiting its relation to some essential characteristic of all intelligent or emotional perception. It is a hard saying, but it is true; and I do not see how to make it any easier. In making these little formal alterations you are beaten by the very nature of things. You are pitted against too skilful an adversary, who will see to it that the pea is always under the other thimble.

Reformation must begin at the other end. First, you must make up your mind as to those quantitative aspects of the world which are simple enough to be introduced into general education; then a schedule of algebra should be framed which will about find its exemplification in these applications. We need not fear for our pet graphs, they will be there in plenty when we once begin to treat algebra as a serious means of studying the world. Some of the simplest applications will be found in the quantities which occur in the simplest study of society. The curves of history are more vivid and more informing than the dry catalogues of names and dates which comprise the greater part of that arid school study. What purpose is effected by a catalogue of undistinguished kings and queens? Tom, Dick, or Harry, they are all dead. General resurrections are failures, and are better postponed. The quantitative flux of the forces of modern society are capable of very simple exhibition. Meanwhile, the idea of the variable, of the function, of rate of change, of equations and their solution, of elimination, are being studied as an abstract science for their own sake. Not, of course, in the pompous phrases with which I am alluding to them here, but with that iteration of simple special cases proper to teaching.

If this course be followed, the route from Chaucer to the Black Death, from the Black Death to modern Labour troubles, will connect the tales of the mediæval pilgrims with the abstract science of algebra, both yielding diverse aspects of that single theme, Life. I know what most of you are thinking at this point. It is that the exact course which I have sketched out is not the particular one which you would have chosen, or even see how to work. I quite agree. I am not claiming that I could do it myself. But your objection is the precise reason why a common external examination system is fatal to education. The process of exhibiting the applications of knowledge must, for its success, essentially depend on the character of the pupils and the genius of the teacher. Of course I have left out the easiest applications with which most of us are more at home. I mean the quantitative sides of sciences, such as mechanics and physics.

My meaning can be illustrated by looking more closely into a special case of this type of application. In my rough catalogue of the sort of subjects which should form the schedule for algebra, I mentioned Elimination. It was not put there by accident, for it covers a very important body of thought.

In the first place, there is the abstract process of algebraic elimination for suitable simple cases. The pupil acquires a firm grasp of this by the process, inevitable in education, of working an adequate number of examples. Again, there are the graphical solutions of the same problem. Then we consider the significance in the external world. We consider the velocity, time, space, acceleration diagrams. We take uniform acceleration; we eliminate "_t_" between

_v_ = _u_ + _ƒt_, and _s_ = _ut_ + ½_ƒt_^2,

and eliminate "_s_" between

_v_^2 = _u_^2 + 2_ƒs_, and _s_ = _ut_ + ½_ƒt_^2.

Then we remember that constant acceleration is a very special case, and we consider graphical solutions or empirically given variations of _v_ or of _ƒ_. In preference, we use those empirical formulæ which occur in the pupil's experimental work. We compare the strong and weak points of the algebraic and graphical solutions.

Again, in the same connection we plot the statistics of social phenomena against the time. We then eliminate the time between suitable pairs. We can speculate how far we have exhibited a real casual connection, or how far a mere temporal coincidence. We notice that we might have plotted against the time one set of statistics for one country and another set for another country, and thus, with suitable choice of subjects, have obtained graphs which certainly exhibited mere coincidence. Also other graphs exhibit obvious casual connections. We wonder how to discriminate. And so are drawn on as far as we will.

But in considering this description, I must beg you to remember what I have been insisting on above. In the first place, one train of thought will not suit all groups of children. For example, I should expect that artisan children will want something more concrete and, in a sense, swifter than I have set down here. Perhaps I am wrong, but that is what I should guess. In the second place, I am not contemplating one beautiful lecture stimulating, once and for all, an admiring class. That is not the way in which education proceeds. No; all the time the pupils are hard at work solving examples, drawing graphs, and making experiments, until they have a thorough hold on the whole subject. I am describing the interspersed explanations, the directions which should be given to their thoughts. The pupils have got to be made to feel that they are studying something, and are not merely executing intellectual minuets.

In this connection the excellence of some of the most recent text-books on elementary algebra emanating from members of this Association, should create an epoch in the teaching of the subject.

Finally, if you are teaching pupils for some general examination, the problem of sound teaching is greatly complicated. Have you ever noticed the zig-zag moulding round a Norman arch? The ancient work is beautiful, the modern work is hideous. The reason is, that the modern work is done to exact measure, the ancient work is varied according to the idiosyncrasy of the workman. Here it is crowded, and there it is expanded. Now the essence of getting pupils through examinations is to give equal weight to all parts of the schedule. But mankind is naturally specialist. One man sees a whole subject, where another can find only a few detached examples. I know that it seems contradictory to allow for specialism in a curriculum especially designed for a broad culture. Without contradictions the world would be simpler, and perhaps duller. But I am certain that in education wherever you exclude specialism you destroy life.

We now come to the other great branch of a general mathematical education, namely Geometry. The same principles apply. The theoretical part should be clear-cut, rigid, short, and important. Every proposition not absolutely necessary to exhibit the main connection of ideas should be cut out, but the great fundamental ideas should be all there. No omission of concepts, such as those of Similarity and Proportion. We must remember that, owing to the aid rendered by the visual presence of a figure, Geometry is a field of unequalled excellence for the exercise of the deductive faculties of reasoning. Then, of course, there follows Geometrical Drawing, with its training for the hand and eye.

But, like Algebra, Geometry and Geometrical Drawing must be extended beyond the mere circle of geometrical ideas. In an industrial neighbourhood, machinery and workshop practice form the appropriate extension. For example, in the London Polytechnics this has been achieved with conspicuous success. For many secondary schools I suggest that surveying and maps are the natural applications. In particular, plane-table surveying should lead pupils to a vivid apprehension of the immediate application of geometric truths. Simple drawing apparatus, a surveyor's chain, and a surveyor's compass, should enable the pupils to rise from the survey and mensuration of a field to the construction of the map of a small district. The best education is to be found in gaining the utmost information from the simplest apparatus. The provision of elaborate instruments is greatly to be deprecated. To have constructed the map of a small district, to have considered its roads, its contours, its geology, its climate, its relation to other districts, the effects on the status of its inhabitants, will teach more history and geography than any knowledge of Perkin Warbeck or of Behren's Straits. I mean not a nebulous lecture on the subject, but a serious investigation in which the real facts are definitely ascertained by the aid of accurate theoretical knowledge. A typical mathematical problem should be: Survey such and such a field, draw a plan of it to such and such a scale, and find the area. It would be quite a good procedure to impart the necessary geometrical propositions without their proofs. Then, concurrently in the same term, the proofs of the propositions would be learnt while the survey was being made.

Fortunately, the specialist side of education presents an easier problem than does the provision of a general culture. For this there are many reasons. One is that many of the principles of procedure to be observed are the same in both cases, and it is unnecessary to recapitulate. Another reason is that specialist training takes place--or should take place--at a more advanced stage of the pupil's course, and thus there is easier material to work upon. But undoubtedly the chief reason is that the specialist study is normally a study of peculiar interest to the student. He is studying it because, for some reason, he wants to know it. This makes all the difference. The general culture is designed to foster an activity of mind; the specialist course utilises this activity. But it does not do to lay too much stress on these neat antitheses. As we have already seen, in the general course foci of special interest will arise; and similarly in the special study, the external connections of the subject drag thought outwards.

Again, there is not one course of study which merely gives general culture, and another which gives special knowledge. The subjects pursued for the sake of a general education are special subjects specially studied; and, on the other hand, one of the ways of encouraging general mental activity is to foster a special devotion. You may not divide the seamless coat of learning. What education has to impart is an intimate sense for the power of ideas, for the beauty of ideas, and for the structure of ideas, together with a particular body of knowledge which has peculiar reference to the life of the being possessing it.

The appreciation of the structure of ideas is that side of a cultured mind which can only grow under the influence of a special study. I mean that eye for the whole chess-board, for the bearing of one set of ideas on another. Nothing but a special study can give any appreciation for the exact formulation of general ideas, for their relations when formulated, for their service in the comprehension of life. A mind so disciplined should be both more abstract and more concrete. It has been trained in the comprehension of abstract thought and in the analysis of facts.

Finally, there should grow the most austere of all mental qualities; I mean the sense for style. It is an æsthetic sense, based on admiration for the direct attainment of a foreseen end, simply and without waste. Style in art, style in literature, style in science, style in logic, style in practical execution have fundamentally the same æsthetic qualities, namely, attainment and restraint. The love of a subject in itself and for itself, where it is not the sleepy pleasure of pacing a mental quarter-deck, is the love of style as manifested in that study.

Here we are brought back to the position from which we started, the utility of education. Style, in its finest sense, is the last acquirement of the educated mind; it is also the most useful. It pervades the whole being. The administrator with a sense for style, hates waste; the engineer with a sense for style, economises his material; the artisan with a sense for style, prefers good work. Style is the ultimate morality of mind.

But above style, and above knowledge, there is something, a vague shape like fate above the Greek gods. That something is Power. Style is the fashioning of power, the restraining of power. But, after all, the power of attainment of the desired end is fundamental. The first thing is to get there. Do not bother about your style, but solve your problem, justify the ways of God to man, administer your province, or do whatever else is set before you.

Where, then, does style help? In this, with style the end is attained without side issues, without raising undesirable inflammations. With style you attain your end and nothing but your end. With style the effect of your activity is calculable, and foresight is the last gift of gods to men. With style your power is increased, for your mind is not distracted with irrelevancies, and you are more likely to attain your object. Now style is the exclusive privilege of the expert. Whoever heard of the style of an amateur painter, of the style of an amateur poet? Style is always the product of specialist study, the peculiar contribution of specialism to culture.

English education in its present phase suffers from a lack of definite aim, and from an external machinery which kills its vitality. Hitherto in this address I have been considering the aims which should govern education. In this respect England halts between two opinions. It has not decided whether to produce amateurs or experts. The profound change in the world which the nineteenth century has produced is that the growth of knowledge has given foresight. The amateur is essentially a man with appreciation and with immense versatility in mastering a given routine. But he lacks the foresight which comes from special knowledge. The object of this address is to suggest how to produce the expert without loss of the essential virtues of the amateur. The machinery of our secondary education is rigid where it should be yielding, and lax where it should be rigid. Every school is bound on pain of extinction to train its boys for a small set of definite examinations. No headmaster has a free hand to develop his general education or his specialist studies in accordance with the opportunities of his school, which are created by its staff, its environment, its class of boys, and its endowments. I suggest that no system of external tests which aims primarily at examining individual scholars can result in anything but educational waste.

Primarily it is the schools and not the scholars which should be inspected. Each school should grant its own leaving certificates, based on its own curriculum. The standards of these schools should be sampled and corrected. But the first requisite for educational reform is the school as a unit, with its approved curriculum based on its own needs, and evolved by its own staff. If we fail to secure that, we simply fall from one formalism into another, from one dung-hill of inert ideas into another.

In stating that the school is the true educational unit in any national system for the safe-guarding of efficiency, I have conceived the alternative system as being the external examination of the individual scholar. But every Scylla is faced by its Charybdis--or, in more homely language, there is a ditch on both sides of the road. It will be equally fatal to education if we fall into the hands of a supervising department which is under the impression that it can divide all schools into two or three rigid categories, each type being forced to adopt a rigid curriculum. When I say that the school is the educational unit, I mean exactly what I say, no larger unit, no smaller unit. Each school must have the claim to be considered in relation to its special circumstances. The classifying of schools for some purposes is necessary. But no absolutely rigid curriculum, not modified by its own staff, should be permissible. Exactly the same principles apply, with the proper modifications, to universities and to technical colleges.

When one considers in its length and in its breadth the importance of this question of the education of a nation's young, the broken lives, the defeated hopes, the national failures, which result from the frivolous inertia with which it is treated, it is difficult to restrain within oneself a savage rage. In the conditions of modern life the ride is absolute, the race which does not value trained intelligence is doomed. Not all your heroism, not all your social charm, not all your wit, not all your victories on land or at sea, can move back the finger of fate. To-day we maintain ourselves. To-morrow science will have moved forward yet one more step, and there will be no appeal from the judgment which will then be pronounced on the uneducated.

We can be content with no less than the old summary of educational ideal which has been current at any time from the dawn of our civilisation. The essence of education is that it be religious.

Pray, what is religious education?

A religious education is an education which inculcates duty and reverence. Duty arises from our potential control over the course of events. Where attainable knowledge could have changed the issue, ignorance has the guilt of vice. And the foundation of reverence is this perception, that the present holds within itself the complete sum of existence, backwards and forwards, that whole amplitude of time, which is eternity.

CHAPTER II

TECHNICAL EDUCATION AND ITS RELATION TO SCIENCE AND LITERATURE

(_Presidential Address to the Mathematical Association, January, 1917_)

THE subject of this address is Technical Education. I wish to examine its essential nature and also its relation to a liberal education. Such an inquiry may help us to realise the conditions for the successful working of a national system of technical training. It is also a very burning question among mathematical teachers; for mathematics is included in most technological courses.

Now it is unpractical to plunge into such a discussion without framing in our own minds the best ideal towards which we desire to work, however modestly we may frame our hopes as to the result which in the near future is likely to be achieved.

People are shy of ideals; and accordingly we find a formulation of the ideal state of mankind placed by a modern dramatist[1] in the mouth of a mad priest: "In my dreams it is a country where the State is the Church and the Church the people: three in one and one in three. It is a commonwealth in which work is play and play is life: three in one and one in three. It is a temple in which the priest is the worshipper and the worshipper the worshipped: three in one and one in three. It is a godhead in which all life is human and all humanity divine: three in one and one in three. It is, in short, the dream of a madman."

Now the part of this speech to which I would direct attention is embodied in the phrase, "It is a commonwealth in which work is play and play is life." This is the ideal of technical education. It sounds very mystical when we confront it with the actual facts, the toiling millions, tired, discontented, mentally indifferent, and then the employers---- I am not undertaking a social analysis, but I shall carry you with me when I admit that the present facts of society are a long way off this ideal. Furthermore, we are agreed that an employer who conducted his workshop on the principle that "work should be play" would be ruined in a week.

The curse that has been laid on humanity, in fable and in fact, is, that by the sweat of its brow shall it live. But reason and moral intuition have seen in this curse the foundation for advance. The early Benedictine monks rejoiced in their labours because they conceived themselves as thereby made fellow-workers with Christ.

Stripped of its theological trappings, the essential idea remains, that work should be transfused with intellectual and moral vision and thereby turned into a joy, triumphing over its weariness and its pain. Each of us will re-state this abstract formulation in a more concrete shape in accordance with his private outlook. State it how you like, so long as you do not lose the main point in your details. However you phrase it, it remains the sole real hope of toiling humanity; and it is in the hands of technical teachers, and of those who control their spheres of activity, so to mould the nation that daily it may pass to its labours in the spirit of the monks of old.

The immediate need of the nation is a large supply of skilled workmen, of men with inventive genius, and of employers alert in the development of new ideas.

There is one--and only one--way to obtain these admirable results. It is by producing workmen, men of science, and employers who enjoy their work. View the matter practically in the light of our knowledge of average human nature. Is it likely that a tired, bored workman, however skilful his hands, will produce a large output of first-class work? He will limit his production, will scamp his work, and be an adept at evading inspection; he will be slow in adapting himself to new methods; he will be a focus of discontent, full of unpractical revolutionary ideas, controlled by no sympathetic apprehension of the real working of trade conditions. If, in the troubled times which may be before us, you wish appreciably to increase the chance of some savage upheaval, introduce widespread technical education and ignore the Benedictine ideal. Society will then get what it deserves.

Again, inventive genius requires pleasurable mental activity as a condition for its vigorous exercise. "Necessity is the mother of invention" is a silly proverb. "Necessity is the mother of futile dodges" is much nearer to the truth. The basis of the growth of modern invention is science, and science is almost wholly the outgrowth of pleasurable intellectual curiosity.

The third class are the employers, who are to be enterprising. Now it is to be observed that it is the successful employers who are the important people to get at, the men with business connections all over the world, men who are already rich. No doubt there will always be a continuous process of rise and fall of businesses. But it is futile to expect flourishing trade, if in the mass the successful houses of business are suffering from atrophy. Now if these men conceive their businesses as merely indifferent means for acquiring other disconnected opportunities of life, they have no spur to alertness. They are already doing very well, the mere momentum of their present business engagements will carry them on for their time. They are not at all likely to bother themselves with the doubtful chances of new methods. Their real soul is in the other side of their life. Desire for money will produce

hard-fistedness and not enterprise. There is much more hope for humanity from manufacturers who enjoy their work than from those who continue in irksome business with the object of founding hospitals.

Finally, there can be no prospect of industrial peace so long as masters and men in the mass conceive themselves as engaged in a soulless operation of extracting money from the public. Enlarged views of the work performed, and of the communal service thereby rendered, can be the only basis on which to found sympathetic co-operation.

The conclusion to be drawn from this discussion is, that alike for masters and for men a technical or technological education, which is to have any chance of satisfying the practical needs of the nation, must be conceived in a liberal spirit as a real intellectual enlightenment in regard to principles applied and services rendered. In such an education geometry and poetry are as essential as turning lathes.

The mythical figure of Plato may stand for modern liberal education as does that of St. Benedict for technical education. We need not entangle ourselves in the qualifications necessary for a balanced representation of the actual thoughts of the actual men. They are used here as symbolic figures typical of antithetical notions. We consider Plato in the light of the type of culture he now inspires.

In its essence a liberal education is an education for thought and for æsthetic appreciation. It proceeds by imparting a knowledge of the masterpieces of thought, of imaginative literature, and of art. The action which it contemplates is command. It is an aristocratic education implying leisure. This Platonic ideal has rendered imperishable services to European civilisation. It has encouraged art, it has fostered that spirit of disinterested curiosity which is the origin of science, it has maintained the dignity of mind in the face of material force, a dignity which claims freedom of thought. Plato did not, like St. Benedict, bother himself to be a fellow-worker with his slaves; but he must rank among the emancipators of mankind. His type of culture is the peculiar inspiration of the liberal aristocrat, the class from which Europe derives what ordered liberty it now possesses. For centuries, from Pope Nicholas V to the schools of the Jesuits, and from the Jesuits to the modern headmasters of English public schools, this educational ideal has had the strenuous support of the clergy.

For certain people it is a very good education. It suits their type of mind and the circumstances amid which their life is passed. But more has been claimed for it than this. All education has been judged adequate or defective according to its approximation to this sole type.

The essence of the type is a large discursive knowledge of the best literature. The ideal product of the type is the man who is acquainted with the best that has been written. He will have acquired the chief languages, he will have considered the histories of the rise and fall of nations, the poetic expression of human feeling, and have read the great dramas and novels. He will also be well grounded in the chief philosophies, and have attentively read those philosophic authors who are distinguished for lucidity of style.

It is obvious that, except at the close of a long life, he will not have much time for anything else if any approximation is to be made to the fulfilment of this programme. One is reminded of the calculation in a dialogue of Lucian that, before a man could be justified in practising any one of the current ethical systems, he should have spent a hundred and fifty years in examining their credentials.

Such ideals are not for human beings. What is meant by a liberal culture is nothing so ambitious as a full acquaintance with the varied literary expression of civilised mankind from Asia to Europe, and from Europe to America. A small selection only is required; but then, as we are told, it is a selection of the very best. I have my doubts of a selection which includes Xenophon and omits Confucius, but then I have read neither in the original. The ambitious programme of a liberal education really shrinks to a study of some fragments of literature included in a couple of important languages.

But the expression of the human spirit is not confined to literature. There are the other arts, and there are the sciences. Also education must pass beyond the passive reception of the ideas of others. Powers of initiative must be strengthened. Unfortunately initiative does not mean just one acquirement--there is initiative in thought, initiative in action, and the imaginative initiative of art; and these three categories require many subdivisions.

The field of acquirement is large, and the individual so fleeting and so fragmentary: classical scholars, scientists, headmasters are alike ignoramuses.

There is a curious illusion that a more complete culture was possible when there was less to know. Surely the only gain was, that it was more possible to remain unconscious of ignorance. It cannot have been a gain to Plato to have read neither Shakespeare, nor Newton, nor Darwin. The achievements of a liberal education have in recent times not been worsened. The change is that its

pretensions have been found out.

My point is, that no course of study can claim any position of ideal completeness. Nor are the omitted factors of subordinate importance. The insistence in the Platonic culture on disinterested intellectual appreciation is a psychological error. Action and our implication in the transition of events amid the evitable bond of cause to effect are fundamental. An education which strives to divorce intellectual or æsthetic life from these fundamental facts carries with it the decadence of civilisation. Essentially culture should be for action, and its effect should be to divest labour from the associations of aimless toil. Art exists that we may know the deliverances of our senses as good. It heightens the sense-world.

Disinterested scientific curiosity is a passion for an ordered intellectual vision of the connection of events. But the goal of such curiosity is the marriage of action to thought. This essential intervention of action even in abstract science is often overlooked. No man of science wants merely to know. He acquires knowledge to appease his passion for discovery. He does not discover in order to know, he knows in order to discover. The pleasure which art and science can give to toil is the enjoyment which arises from successfully directed intention. Also it is the same pleasure which is yielded to the scientist and to the artist.

The antithesis between a technical and a liberal education is fallacious. There can be no adequate technical education which is not liberal, and no liberal education which is not technical: that is, no education which does not impart both technique and intellectual vision. In simpler language, education should turn out the pupil with something he knows well and something he can do well. This intimate union of practice and theory aids both. The intellect does not work best in a vacuum. The stimulation of creative impulse requires, especially in the case of a child, the quick transition to practice. Geometry and mechanics, followed by workshop practice, gain that reality without which mathematics is verbiage.

There are three main methods which are required in a national system of education, namely, the literary curriculum, the scientific curriculum, the technical curriculum. But each of these curricula should include the other two. What I mean is, that every form of education should give the pupil a technique, a science, an assortment of general ideas, and æsthetic appreciation, and that each of these sides of his training should be illuminated by the others. Lack of time, even for the most favoured pupil, makes it impossible to develop fully each curriculum. Always there must be a dominant emphasis. The most direct æsthetic training naturally falls in the technical curriculum in those cases when the training is that requisite for some art or artistic craft. But it is of high importance in both a literary and a scientific education.

The educational method of the literary curriculum is the study of language, that is, the study of our most habitual method of conveying to others our states of mind. The technique which should be acquired is the technique of verbal expression, the science is the study of the structure of language and the analysis of the relations of language to the states of mind conveyed. Furthermore, the subtle relations of language to feeling, and the high development of the sense organs to which written and spoken words appeal, lead to keen æsthetic appreciations being aroused by the successful employment of language. Finally, the wisdom of the world is preserved in the masterpieces of linguistic composition.

This curriculum has the merit of homogeneity. All its various parts are co-ordinated and play into each other's hands. We can hardly be surprised that such a curriculum, when once broadly established, should have claimed the position of the sole perfect type of education. Its defect is unduly to emphasise the importance of language. Indeed the varied importance of verbal expression is so overwhelming that its sober estimation is difficult. Recent generations have been witnessing the retreat of literature, and of literary forms of expression, from their position of unique importance in intellectual life. In order truly to become a servant and a minister of nature something more is required than literary aptitudes.

A scientific education is primarily a training in the art of observing natural phenomena, and in the knowledge and deduction of laws concerning the sequence of such phenomena. But here, as in the case of a liberal education, we are met by the limitations imposed by shortness of time. There are many types of natural phenomena, and to each type there corresponds a science with its peculiar modes of observation, and its peculiar types of thought employed in the deduction of laws. A study of science in general is impossible in education, all that can be achieved is the study of two or three allied sciences. Hence the charge of narrow specialism urged against any education which is primarily scientific. It is obvious that the charge is apt to be well-founded; and it is worth considering how, within the limits of a scientific education and to the advantage of such an education, the danger can be avoided.

Such a discussion requires the consideration of technical education. A technical education is in the main a training in the art of utilising knowledge for the manufacture of material products. Such a training emphasises manual skill, and the co-ordinated action of hand and eye, and judgment in the control of the process of construction. But judgment necessitates knowledge of those natural

processes of which the manufacture is the utilisation. Thus somewhere in technical training an education in scientific knowledge is required. If you minimise the scientific side, you will confine it to the scientific experts; if you maximise it, you will impart it in some measure to the men, and--what is of no less importance--to the directors and managers of the businesses.

Technical education is not necessarily allied exclusively to science on its mental side. It may be an education for an artist or for apprentices to an artistic craft. In that case æsthetic appreciation will have to be cultivated in connection with it.

An evil side of the Platonic culture has been its total neglect of technical education as an ingredient in the complete development of ideal human beings. This neglect has arisen from two disastrous antitheses, namely, that between mind and body, and that between thought and action. I will here interject, solely to avoid criticism, that I am well aware that the Greeks highly valued physical beauty and physical activity. They had, however, that perverted sense of values which is the nemesis of slave-owning.

I lay it down as an educational axiom that in teaching you will come to grief as soon as you forget that your pupils have bodies. This is exactly the mistake of the post-renaissance Platonic curriculum. But nature can be kept at bay by no pitchfork; so in English education, being expelled from the classroom, she returned with a cap and bells in the form of all-conquering athleticism.

The connections between intellectual activity and the body, though diffused in every bodily feeling, are focussed in the eyes, the ears, the voice, and the hands. There is a co-ordination of senses and thought, and also a reciprocal influence between brain activity and material creative activity. In this reaction the hands are peculiarly important. It is a moot point whether the human hand created the human brain, or the brain created the hand. Certainly the connection is intimate and reciprocal. Such deep-seated relations are not widely atrophied by a few hundred years of disuse in exceptional families.

The disuse of hand-craft is a contributory cause to the brain-lethargy of aristocracies, which is only mitigated by sport where the concurrent brain-activity is reduced to a minimum and the hand-craft lacks subtlety. The necessity for constant writing and vocal exposition is some slight stimulus to the thought-power of the professional classes. Great readers, who exclude other activities, are not distinguished by subtlety of brain. They tend to be timid conventional thinkers. No doubt this is partly due to their excessive knowledge outrunning their powers of thought; but it is partly due to the lack of brain-stimulus from the productive activities of hand or voice.

In estimating the importance of technical education we must rise above the exclusive association of learning with book-learning. First-hand knowledge is the ultimate basis of intellectual life. To a large extent book-learning conveys second-hand information, and as such can never rise to the importance of immediate practice. Our goal is to see the immediate event of our lives as instances of our general ideas. What the learned world tends to offer is one second-hand scrap of information illustrating ideas derived from another second-hand scrap of information. The second-handedness of the learned world is the secret of its mediocrity. It is tame because it has never been scared by facts. The main importance of Francis Bacon's influence does not lie in any peculiar theory of inductive reasoning which he happened to express, but in the revolt against second-hand information of which he was a leader.

The peculiar merit of a scientific education should be, that it bases thought upon first-hand observation; and the corresponding merit of a technical education is, that it follows our deep natural instinct to translate thought into manual skill, and manual activity into thought.

We are a Mathematical Association, and it is natural to ask: Where do we come in? We come in just at this point.

The thought which science evokes is logical thought. Now logic is of two kinds: the logic of discovery and the logic of the discovered.

The logic of discovery consists in the weighing of probabilities, in discarding details deemed to be irrelevant, in divining the general rules according to which events occur, and in testing hypotheses by devising suitable experiments. This is inductive logic.

The logic of the discovered is the deduction of the special events which, under certain circumstances, would happen in obedience to the assumed laws of nature. Thus when the laws are discovered or assumed, their utilisation entirely depends on deductive logic. Without deductive logic science would be entirely useless. It is merely a barren game to ascend from the particular to the general, unless afterwards we can reverse the process and descend from the general to the particular, ascending and descending like the angels on Jacob's ladder. When Newton had divined the law of gravitation he at once proceeded to calculate the earth's attractions on an apple at its surface and on the moon. We may note in passing that inductive logic would be impossible without

deductive logic. Thus Newton's calculations were an essential step in his inductive verification of the great law.

Now mathematics is nothing else than the more complicated parts of the art of deductive reasoning, especially where it concerns number, quantity, and space.

In the teaching of science, the art of thought should be taught: namely, the art of forming clear conceptions applying to first-hand experience, the art of divining the general truths which apply, the art of testing divinations, and the art of utilising general truths by reasoning to more particular cases of some peculiar importance. Furthermore, a power of scientific exposition is necessary, so that the relevant issues from a confused mass of ideas can be stated clearly, with due emphasis on important points.

By the time a science, or a small group of sciences, has been taught thus amply, with due regard to the general art of thought, we have gone a long way towards correcting the specialism of science. The worst of a scientific education based, as necessarily must be the case, on one or two particular branches of science, is that the teachers under the influence of the examination system are apt merely to stuff their pupils with the narrow results of these special sciences. It is essential that the generality of the method be continually brought to light and contrasted with the speciality of the particular application. A man who only knows his own science, as a routine peculiar to that science, does not even know that. He has no fertility of thought, no power of quickly seizing the bearing of alien ideas. He will discover nothing, and be stupid in practical applications.

This exhibition of the general in the particular is extremely difficult to effect, especially in the case of younger pupils. The art of education is never easy. To surmount its difficulties, especially those of elementary education, is a task worthy of the highest genius. It is the training of human souls.

Mathematics, well taught, should be the most powerful instrument in gradually implanting this generality of idea. The essence of mathematics is perpetually to be discarding more special ideas in favour of more general ideas, and special methods in favour of general methods. We express the conditions of a special problem in the form of an equation, but that equation will serve for a hundred other problems, scattered through diverse sciences. The general reasoning is always the powerful reasoning, because deductive cogency is the property of abstract form.

Here, again, we must be careful. We shall ruin mathematical education if we use it merely to impress general truths. The general ideas are the means of connecting particular results. After all, it is the concrete special cases which are important. Thus in the handling of mathematics in your results you cannot be too concrete, and in your methods you cannot be too general. The essential course of reasoning is to generalise what is particular, and then to particularise what is general. Without generality there is no reasoning, without concreteness there is no importance.

Concreteness is the strength of technical education. I would remind you that truths which lack the highest generality are not necessarily concrete facts. For example, _x_ + _y_ = _y_ + _x_ is an algebraic truth more general than 2 + 2 = 4. But "two and two make four" is itself a highly general proposition lacking any element of concreteness. To obtain a concrete proposition immediate intuition of a truth concerning particular objects is requisite; for example, "these two apples and those apples together make four apples" is a concrete proposition, if you have direct perception or immediate memory of the apples.

In order to obtain the full realisation of truths as applying, and not as empty formulæ, there is no alternative to technical education. Mere passive observation is not sufficient. In creation only is there vivid insight into the properties of the object thereby produced. If you want to understand anything, make it yourself, is a sound rule. Your faculties will be alive, your thoughts gain vividness by an immediate translation into acts. Your ideas gain that reality which comes from seeing the limits of their application.

In elementary education this doctrine has long been put into practice. Young children are taught to familiarise themselves with shapes and colours by simple manual operations of cutting out and of sorting. But good though this is, it is not quite what I mean. That is practical experience before you think, experience antecedent to thought in order to create ideas, a very excellent discipline. But technical education should be much more than that: it is creative experience while you think, experience which realises your thought, experience which teaches you to co-ordinate act and thought, experience leading you to associate thought with foresight and foresight with achievement. Technical education gives theory, and a shrewd insight as to where theory fails.

A technical education is not to be conceived as a maimed alternative to the perfect Platonic culture: namely, as a defective training unfortunately made necessary by cramped conditions of life. No human being can attain to anything but fragmentary knowledge and a fragmentary training of his capacities. There are, however, three main roads along which we can proceed with good hope of advancing towards the best balance of intellect and character: these are the way of literary culture, the way of scientific culture, the

way of technical culture. No one of these methods can be exclusively followed without grave loss of intellectual activity and of character. But a mere mechanical mixture of the three curricula will produce bad results in the shape of scraps of information never interconnected or utilised. We have already noted as one of the strong points of the traditional literary culture that all its parts are co-ordinated. The problem of education is to retain the dominant emphasis, whether literary, scientific, or technical, and without loss of co-ordination to infuse into each way of education something of the other two.

To make definite the problem of technical education fix attention on two ages: one thirteen, when elementary education ends; and the other seventeen, when technical education ends so far as it is compressed within a school curriculum. I am aware that for artisans in junior technical schools a three-years' course would be more usual. On the other hand, for naval officers, and for directing classes generally, a longer time can be afforded. We want to consider the principles to govern a curriculum which shall land these children at the age of seventeen in the position of having technical skill useful to the community.

Their technical manual training should start at thirteen, bearing a modest proportion to the rest of their work, and should increase in each year finally to attain to a substantial proportion. Above all things it should not be too specialised. Workshop finish and workshop dodges, adapted to one particular job, should be taught in the commercial workshop, and should form no essential part of the school course. A properly trained worker would pick them up in no time. In all education the main cause of failure is staleness. Technical education is doomed if we conceive it as a system for catching children young and for giving them one highly specialised manual aptitude. The nation has need of a fluidity of labour, not merely from place to place, but also within reasonable limits of allied aptitudes, from one special type of work to another special type. I know that here I am on delicate ground, and I am not claiming that men while they are specialising on one sort of work should spasmodically be set to other kinds. That is a question of trade organisation with which educationalists have no concern. I am only asserting the principles that training should be broader than the ultimate specialisation, and that the resulting power of adaptation to varying demands is advantageous to the workers, to the employers, and to the nation.

In considering the intellectual side of the curriculum we must be guided by the principle of the co-ordination of studies. In general, the intellectual studies most immediately related to manual training will be some branches of science. More than one branch will, in fact, be concerned; and even if that be not the case, it is impossible to narrow down scientific study to a single thin line of thought. It is possible, however, provided that we do not press the classification too far, roughly to classify technical pursuits according to the dominant science involved. We thus find a sixfold division, namely, (1) Geometrical techniques, (2) Mechanical techniques, (3) Physical techniques, (4) Chemical techniques, (5) Biological techniques, (6) Techniques of commerce and of social service.

By this division, it is meant that apart from auxiliary sciences some particular science requires emphasis in the training for most occupations. We can, for example, reckon carpentry, ironmongery, and many artistic crafts among geometrical techniques. Similarly agriculture is a biological technique. Probably cookery, if it includes food catering, would fall midway between biological, physical, and chemical sciences, though of this I am not sure.

The sciences associated with commerce and social service would be partly algebra, including arithmetic and statistics, and partly geography and history. But this section is somewhat heterogeneous in its scientific affinities. Anyhow the exact way in which technical pursuits are classified in relation to science is a detail. The essential point is, that with some thought it is possible to find scientific courses which illuminate most occupations. Furthermore, the problem is well understood, and has been brilliantly solved in many of the schools of technology and junior technical schools throughout the country.

In passing from science to literature, in our review of the intellectual elements of technical education, we note that many studies hover between the two: for example, history and geography. They are both of them very essential in education, provided that they are the right history and the right geography. Also books giving descriptive accounts of general results, and trains of thought in various sciences fall in the same category. Such books should be partly historical and partly expository of the main ideas which have finally arisen. Prof. R. A. Gregory's recent book, _Discovery_, and the _Home University Library_ series illustrate my meaning. Their value in education depends on their quality as mental stimulants. They must not be inflated with gas on the wonders of science, and must be informed with a broad outlook.

It is unfortunate that the literary element in education has rarely been considered apart from grammatical study. The historical reason is, that when the modern Platonic curriculum was being formed Latin and Greek were the sole keys which rendered great literature accessible. But there is no necessary connection between literature and grammar. The great age of Greek literature was already past before the arrival of the grammarians of Alexandria. Of all types of men to-day existing, classical scholars are the most

remote from the Greeks of the Periclean times.

Mere literary knowledge is of slight importance. The only thing that matters is, how it is known. The facts related are nothing. Literature only exists to express and develop that imaginative world which is our life, the kingdom which is within us. It follows that the literary side of a technical education should consist in an effort to make the pupils enjoy literature. It does not matter what they know, but the enjoyment is vital. The great English Universities, under whose direct authority school-children are examined in plays of Shakespeare, to the certain destruction of their enjoyment, should be prosecuted for soul-murder.

Now there are two kinds of intellectual enjoyment: the enjoyment of creation, and the enjoyment of relaxation. They are not necessarily separated. A change of occupation may give the full tide of happiness which comes from the concurrence of both forms of pleasure. The appreciation of literature is really creation. The written word, its music, and its associations, are only the stimuli. The vision which they evoke is our own doing. No one, no genius other than our own, can make our own life live. But except for those engaged in literary occupations, literature is also a relaxation. It gives exercise to that other side which any occupation must suppress during the working hours. Art also has the same function in life as has literature.

To obtain the pleasure of relaxation requires no help. The pleasure is merely to cease doing. Some such pure relaxation is a necessary condition of health. Its dangers are notorious, and to the greater part of the necessary relaxation nature has affixed, not enjoyment, but the oblivion of sleep. Creative enjoyment is the outcome of successful effort and requires help for its initiation. Such enjoyment is necessary for high-speed work and for original achievement.

To speed up production with unrefreshed workmen is a disastrous economic policy. Temporary success will be at the expense of the nation, which, for long years of their lives, will have to support worn-out artisans--unemployables. Equally disastrous is the alternation of spasms of effort with periods of pure relaxation. Such periods are the seed-times of degeneration, unless rigorously curtailed. The normal recreation should be change of activity, satisfying the cravings of instincts. Games afford such activity. Their disconnection emphasises the relaxation, but their excess leaves us empty.

It is here that literature and art should play an essential part in a healthily organised nation. Their services to economic production would be only second to those of sleep or of food. I am not now talking of the training of an artist, but of the use of art as a condition of healthy life. It is analogous to sunshine in the physical world.

When we have once rid our minds of the idea that knowledge is to be exacted, there is no especial difficulty or expense involved in helping the growth of artistic enjoyment. All school-children could be sent at regular intervals to neighbouring theatres where suitable plays could be subsidised. Similarly for concerts and cinema films. Pictures are more doubtful in their popular attraction; but interesting representations of scenes or ideas which the children have read about would probably appeal. The pupils themselves should be encouraged in artistic efforts. Above all the art of reading aloud should be cultivated. The Roger de Coverley essays of Addison are perfect examples of readable prose.

Art and literature have not merely an indirect effect on the main energies of life. Directly, they give vision. The world spreads wide beyond the deliverances of material sense, with subtleties of reaction and with pulses of emotion. Vision is the necessary antecedent to control and to direction. In the contest of races which in its final issues will be decided in the workshops and not on the battle-field, the victory will belong to those who are masters of stores of trained nervous energy, working under conditions favourable to growth. One such essential condition is Art.

If there had been time, there are other things which I should like to have said: for example, to advocate the inclusion of one foreign language in all education. From direct observation I know this to be possible for artisan children. But enough has been put before you, to make plain the principles with which we should undertake national education.

In conclusion, I recur to the thought of the Benedictines, who saved for mankind the vanishing civilisation of the ancient world by linking together knowledge, labour, and moral energy. Our danger is to conceive practical affairs as the kingdom of evil, in which success is only possible by the extrusion of ideal aims. I believe that such a conception is a fallacy directly negatived by practical experience. In education this error takes the form of a mean view of technical training. Our forefathers in the dark ages saved themselves by embodying high ideals in great organisations. It is our task, without servile imitation, boldly to exercise our creative energies, remembering amid discouragements that the coldest hour immediately precedes the dawn.

FOOTNOTES:

CHAPTER III

A POLYTECHNIC IN WAR-TIME

Address at the Prize Distribution, Borough Polytechnic Institute, Southwark, 16th February, 1917

I WILL commence by drawing your attention to some of the satisfactory features of the Principal's report on the work of the Institute during the past year. It has been a year of great difficulties. Some of our staff are serving with the colours, and our classes have been depleted. But in spite of everything, we have done very well. First, the average result in the examinations has been good, surprisingly good in view of the present circumstances. The Governors attach great importance to the maintenance of a high average result; it is the best single test of efficiency. Again, our individual successes have been notable. We have gained--I say _we_ because we are all one in our pleasure at these successes--we have gained two £80 L.C.C. scholarships, nineteen exhibitions, in addition to a first-place, and medals, prizes and certificates. All this is very satisfactory. It tells of efficient teaching, and of hard work and regular attendance on the part of the students. We know that we are keeping up the standard of efficiency which in the past has been a source of pride to every one connected with this Institute.

Now all this good work does not come about by itself without any one making an effort. Such a record requires our skilled staff of teachers and organisers. They have worked very hard during the last session under great difficulties, in order to create the successful result which we are here to celebrate. I know something about teaching. It is very exacting work, and can be made successful only by continual devotion. I am sure that I am voicing your feelings, and I know that I am expressing those of the Governors, when I thank the ladies and gentlemen of the staff very heartily for their services during the last session.

Prize-givings are always pleasant occasions. We have come here to think about our successes, and to congratulate our students. There is no more satisfactory Governors' Meeting in the course of the year than when we meet on this occasion, and face our friends and tell them how pleased we are at the successful result of their hard work. This evening I am in a doubly happy position, for my colleagues have asked me to be their spokesman in tendering our good wishes to the prize-winners. You have worked hard and you have done well, and I am sure that you all deserve your successes; they are a pleasure not only to you, but in your homes and to your companions and fellow-students.

Successful work here will enable you to acquire skill in your trades, and thereby the better to earn your living. Earning a living is on the average no bad test of service rendered to the community. A man who has made himself skilful in his trade and has done well for himself in his walk of life, has in general good reason to believe that he is a citizen who has benefited his country. It is an evil day for a nation when it loses respect for success in industry.

But if you steer your lives by the compass which points steadily to the North Pole of personal success, you will have missed your greatest chances in life. The genial climate is in the south.

What I mean is this: you must make up your mind to find the best part of your happiness in kindly helpful relations with others. It should be our ambition to leave our own small corner of the world a little tidier and a little happier than when we entered it. I am well aware that this is an old story; but old stories are sometimes true, and this is the biggest truth in the whole world. The warm kindly feelings are the happy feelings. The fortunate people are those whose minds are filled with thoughts in which they forget themselves and remember others. It is not true that nature is a mere scene of struggle in which every one competes with his neighbour. Those communities thrive best and last longest which are filled with a spirit of mutual help.

The future of the country lies with you. The crown of your success is the promise of future work, often unrecognised work, done under discouragement, but done steadily and cheerfully. It is on you that the country depends for the maintenance and the growth of those ideals without which a race withers. Do not be discouraged by difficulties which seem unsurmountable. The conditions of life which mould us all are modified by our will, by our energy, and by the purity of our intentions.

If we may judge of intensity of feeling by length of memory, the enjoyment of receiving a prize bites very deep. Across the space of more than forty years, before many of your parents were born, or when they were being carried about in long clothes, I can remember, as if it were yesterday, the occasion when I received my first prize at school. I can see the mediæval school-room, the headmaster, and my companions. Perhaps some of you, when a generation has passed by, will remember the scene to-night--this Stanley Gymnasium recalling the memory of Miss Maude Stanley, who devoted to our welfare so much of her energy and her

thought--the adjoining Edric Hall associated with the name of Mr. Edric Bayley, the Father of the Institute; Mr. Millis and Miss Smith, the first Principal and the first Lady Superintendent, the architects of our prosperity; Mr. Leonard Spicer, our Chairman and member of a family and of a firm known throughout the world, and respected in proportion as they are known. And the cause why to-night we are a small gathering is one more reason why this assembly can never slip from your memory. We meet at a moment when England stands in as deadly a peril as in any previous moment of her history--such peril as when the Spanish ships of the Armada rode in the English Channel, or when Napoleon watched our coast across the Strait of Dover. The present danger can be overcome only by the same courage as that which saved our freedom in those former times.

Therefore, to-night, in recalling the activities of the various sections of our society which form this great Polytechnic Institute, our thoughts go further afield. They travel by land and by sea, till they bring before our minds the gallant band whom this Institute has sent to the Front--more than 800 of our members are with the Colours. What our fighting men have done for us, for the world in general, and for the future of England, is so overwhelming that words cannot praise them enough. I will just say one thing to you: When you read of great deeds done in past times, of perils encountered, of adventures, of undaunted courage, of patriotism, of self-sacrifice, of suffering endured for noble cause, you each can say--I, too, have known such heroes; they are among my countrymen, they are among my fellow-workers, they are among my fellow-students and companions, they are among the dear inmates of my home. And for those who have fallen, it is for us to erect a monument sufficient to transmit to future ages the memory of their sacrifice. For this purpose there is only one memorial which can suffice, namely, the cause for which they died. The greatness of England, the future of England, has been left by them to our keeping. Guard it well.

The greatness of a country is nothing else than the greatness of the lives of the men and of the women who compose it. Do not look round and think who ought to be great Englishmen--be great yourselves--you are the people to achieve it, you who are sitting here to-night. There can be no substitute service for this purpose. It is the collective energy of the whole people that will be needed to fashion a new England worthy of the sufferings which for its sake have been endured.

A few days ago I asked a man who has worked in Egypt for many years under Lord Kitchener, what he would pick out as the best sign of Lord Kitchener's greatness. He answered, whatever Kitchener set himself to do, thereby became important. Now that is the secret of it all--take hold of your opportunities and make them important.

Here we are in this Borough Polytechnic. What an opportunity it represents. This Institute is a centre for social meeting, a centre for recreation, a centre for education, a centre for discussion. We will not sacrifice any one of our sides. They must all be part of the greatness which we claim. Make them all first-rate.

Consider first the social and recreative sides. For heaven's sake don't think that you must be dull in order to be great. There is no finer test of a nation than the way in which it fashions its amusements. Three centuries ago after the Armada we made a good start in Southwark. Shakespeare had his theatre here and wrote his plays to be acted in this borough. He has walked these streets, and if you had met him in Westminster he would, quite likely, have told you that he was going down to the "Elephant." And even now the performances given at the "Old Vic" are among the best in London for the purpose of seeing his plays properly acted. What Southwark has done for the drama, she can do for the other arts, by using this Institute as the instrument for her energies. Why should we not be a centre for artistic enterprise--I mean for our own art and our own enterprise, thought of by ourselves and enjoyed by ourselves and carried through by ourselves? We shall not always enjoy each others' creations, but the great point is to make our own efforts. Of course all efforts require preparation and stimulus and knowledge of what others are doing.

At the present time--interrupted for the moment by the war--a great revolution in the art of painting is in progress throughout the world. Its centres are Paris and Italy and London and Munich, and its origin in the far east, in China and Japan. There are two sides as in every revolution, the Conservatives and the Revolutionists. Our own frescoes in a neighbouring room represent an early stage of the movement in London. Why should we not know all about it--obtain loans of pictures which illustrate its phases and its cross currents, and compare these with examples of the old style?

But pictures are only one phase of art, and not the sort of art which we ourselves can produce most easily. There are music, dancing, recitation, literature, carving and modelling, and the various decorative arts, such as embroidery, bookbinding, dress-making and upholstery. This list, incomplete as it is, tells us two great truths--you cannot separate art and recreation, and you cannot separate art and business. The list includes items which we consider as amusements, and items which we think of as business. We began with dancing and ended with upholstery. Make them all beautiful.

Beautiful things have dignity. Enjoy the rhythm of your dancing and admire the beauty of your embroidery or your bookbinding. In whatever you do, have an ideal of excellence. Any separation between art and work is not only an error, but it is very bad business. Our brave allies, the French, have made Paris the art centre of the world. They have built up and maintain their large and lucrative trade in the decorative products of France, mainly by reason of three qualities which they possess. In the first place, they enjoy art themselves, and reverence it. In the second place, they have a tremendous power of hard work. And in the third place, every Frenchman, and still more every Frenchwoman, have within them an immense fund of common sense. The threefold secret is, Love of Art, Industry, and Common Sense.

To make available our industry and common sense in the trades where they are wanted, rigorous training in schools of design and technique are necessary. We have such departments here. But all such training of you will be a failure unless you yourselves enjoy art and beauty as a natural recreation. A technical school of training is like a deep, narrow well, sunk with careful labour to tap the underground river of water which flows below the surface of our natures. But your well will be dry unless the bright warm sun has first drawn up the vapour from the wide ocean, and the free untrammelled breezes have carried the clouds hither and thither, until at length they break, as it were by chance over the distant hills and soak the land with their downpour.

What I have said about art is a parable which applies to other occupations and other studies. It is more than a parable; it is the literal truth. The love of art is the love of excellence, it is the enjoyment of the triumph of design over the shapeless products of chance forces. An engineer, who is worth his salt, loves the beauty of his machines, shown in their adjustment of parts and in their swift, smooth motions. He loves also the sense of foresight and of insight which knowledge can give him. People say that machinery and commerce are driving beauty out of the modern world. I do not believe it. A new beauty is being added, a more intellectual beauty, appealing to the understanding as much as to the eye.

The wonder of London ever takes the mind with fresh astonishment. The city possesses parks, and palaces, and cathedrals. But no other parts of it surpass in wonder its houses of business and its workshops and its factories.

In the next few years the future of the world will be decided for centuries to come. The battles of this war are only the first part of the contest between races, and between the ways of life for which those races stand. We believe that England, with its various peoples and communities scattered in islands and continents beyond the seas, stands for ways of life infinitely precious, the way of humanity, the way of liberty, the way of self-government, the way of good order based on toleration and kindly feeling, the way of peaceful industry. The final decision in this struggle will be found in the workshops of the world. It lies in your hands. Statesmen and emperors will only register the results which you have achieved. Your weapons will be skill, and energy, and knowledge. You will require a sane understanding of your own rights, and a sane understanding of the rights and the difficulties of other classes. The greatness of England will be your greatness, and its success your success.

The arsenal for war is at Woolwich. This Polytechnic Institute is an arsenal for peace, where you can find the weapons for the conquest of your lives.

CHAPTER IV

THE MATHEMATICAL CURRICULUM

(_Presidential Address to the London Branch of the Mathematical Association, 1912_)

THE situation in regard to education at the present time cannot find its parallel without going back for some centuries to the break-up of the mediæval traditions of learning. Then, as now, the traditional intellectual outlook, despite the authority which it had justly acquired from its notable triumphs, had grown to be too narrow for the interests of mankind. The result of this shifting of human interest was a demand for a parallel shifting of the basis of education, so as to fit the pupils for the ideas which later in life would in fact occupy their minds. Any serious fundamental change in the intellectual outlook of human society must necessarily be followed by an educational revolution. It may be delayed for a generation by vested interests or by the passionate attachment of some leaders of thought to the cycle of ideas within which they received their own mental stimulus at an impressionable age. But the law is inexorable that education to be living and effective must be directed to informing pupils with those ideas, and to creating for them those capacities which will enable them to appreciate the current thought of their epoch.

There is no such thing as a successful system of education in a vacuum, that is to say, a system which is divorced from immediate contact with the existing intellectual atmosphere. Education which is not modern shares the fate of all organic things which are kept

too long.

But the blessed word "modern" does not really solve our difficulties. What we mean is, relevant to modern thought, either in the ideas imparted or in the aptitudes produced. Something found out only yesterday may not really be modern in this sense. It may belong to some bygone system of thought prevalent in a previous age, or, what is very much more likely, it may be too recondite. When we demand that education should be relevant to modern thought, we are referring to thoughts broadly spread throughout cultivated society. It is this question of the unfitness of recondite subjects for use in general education which I wish to make the keynote of my address this afternoon.

It is in fact rather a delicate subject for us mathematicians. Outsiders are apt to accuse our subject of being recondite. Let us grasp the nettle at once and frankly admit that in general opinion it is the very typical example of reconditeness. By this word I do not mean difficulty, but that the ideas involved are of highly special application, and rarely influence thought.

This liability to reconditeness is the characteristic evil which is apt to destroy the utility of mathematics in liberal education. So far as it clings to the educational use of the subject, so far we must acquiesce in a miserably low level of mathematical attainment among cultivated people in general. I yield to no one in my anxiety to increase the educational scope of mathematics. The way to achieve this end is not by a mere blind demand for more mathematics. We must face the real difficulty which obstructs its extended use.

Is the subject recondite? Now, viewed as a whole, I think it is. _Securus judicat orbis terrarum_--the general judgment of mankind is sure.

The subject as it exists in the minds and in the books of students of mathematics _is_ recondite. It proceeds by deducing innumerable special results from general ideas, each result more recondite than the preceding. It is not my task this afternoon to defend mathematics as a subject for profound study. It can very well take care of itself. What I want to emphasise is, that the very reasons which make this science a delight to its students are reasons which obstruct its use as an educational instrument--namely, the boundless wealth of deductions from the interplay of general theorems, their complication, their apparent remoteness from the ideas from which the argument started, the variety of methods, and their purely abstract character which brings, as its gift, eternal truth.

Of course, all these characteristics are of priceless value to students; for ages they have fascinated some of the keenest intellects. My only remark is that, except for a highly selected class, they are fatal in education. The pupils are bewildered by a multiplicity of detail, without apparent relevance either to great ideas or to ordinary thoughts. The extension of this sort of training in the direction of acquiring more detail is the last measure to be desired in the interests of education.

The conclusion at which we arrive is, that mathematics, if it is to be used in general education, must be subjected to a rigorous process of selection and adaptation. I do not mean, what is of course obvious, that however much time we devote to the subject the average pupil will not get very far. But that, however limited the progress, certain characteristics of the subject, natural at any stage, must be rigorously excluded. The science as presented to young pupils must lose its aspect of reconditeness. It must, on the face of it, deal directly and simply with a few general ideas of far-reaching importance.

Now, in this matter of the reform of mathematical instruction, the present generation of teachers may take a very legitimate pride in its achievements. It has shown immense energy in reform, and has accomplished more than would have been thought possible in so short a time. It is not always recognised how difficult is the task of changing a well-established curriculum entrenched behind public examinations.

But for all that, great progress has been made, and, to put the matter at its lowest, the old dead tradition has been broken up. I want to indicate this afternoon the guiding idea which should direct our efforts at reconstruction. I have already summed it up in a phrase, namely, we must aim at the elimination of reconditeness from the educational use of the subject.

Our courses of instruction should be planned to illustrate simply a succession of ideas of obvious importance. All pretty divagations should be rigorously excluded. The goal to be aimed at is that the pupil should acquire familiarity with abstract thought, should realise how it applies to particular concrete circumstances, and should know how to apply general methods to its logical investigation. With this educational ideal nothing can be worse than the aimless accretion of theorems in our text-books, which acquire their position merely because the children can be made to learn them and examiners can set neat questions on them. The bookwork to be learnt should all be very important as illustrating ideas. The examples set--and let there be as many examples as teachers find necessary--should be direct illustrations of the theorems, either by way of abstract particular cases or by way of

application to concrete phenomena. Here it is worth remarking that it is quite useless to simplify the bookwork, if the examples set in examinations in fact require an extended knowledge of recondite details. There is a mistaken idea that problems test ability and genius, and that bookwork tests cram. This is not my experience. Only boys who have been specially crammed for scholarships can ever do a problem paper successfully. Bookwork properly set, not in mere snippets according to the usual bad plan, is a far better test of ability, provided that it is supplemented by direct examples. But this is a digression on the bad influence of examinations on teaching.

The main ideas which lie at the base of mathematics are not at all recondite. They are abstract. But one of the main objects of the inclusion of mathematics in a liberal education is to train the pupils to handle abstract ideas. The science constitutes the first large group of abstract ideas which naturally occur to the mind in any precise form. For the purposes of education, mathematics consists of the relations of number, the relations of quantity, and the relations of space. This is not a general definition of mathematics, which, in my opinion, is a much more general science. But we are now discussing the use of mathematics in education. These three groups of relations, concerning number, quantity, and space, are interconnected.

Now, in education we proceed from the particular to the general. Accordingly, children should be taught the use of these ideas by practice among simple examples. My point is this: The goal should be, not an aimless accumulation of special mathematical theorems, but the final recognition that the preceding years of work have illustrated those relations of number, and of quantity, and of space, which are of fundamental importance. Such a training should lie at the base of all philosophical thought. In fact elementary mathematics rightly conceived would give just that philosophical discipline of which the ordinary mind is capable. But what at all costs we ought to avoid, is the pointless accumulation of details. As many examples as you like; let the children work at them for terms, or for years. But these examples should be direct illustrations of the main ideas. In this way, and this only, can the fatal reconditeness be avoided.

I am not now speaking in particular of those who are to be professional mathematicians, or of those who for professional reasons require a knowledge of certain mathematical details. We are considering the liberal education of all students, including these two classes. This general use of mathematics should be the simple study of a few general truths, well illustrated by practical examples. This study should be conceived by itself, and completely separated in idea from the professional study mentioned above, for which it would make a most excellent preparation. Its final stage should be the recognition of the general truths which the work done has illustrated. As far as I can make out, at present the final stage is the proof of some property of circles connected with triangles. Such properties are immensely interesting to mathematicians. But are they not rather recondite, and what is the precise relation of such theorems to the ideal of a liberal education? The end of all the grammatical studies of the student in classics is to read Virgil and Horace--the greatest thoughts of the greatest men. Are we content, when pleading for the adequate representation in education of our own science, to say that the end of a mathematical training is that the student should know the properties of the nine-point circle? I ask you frankly, is it not rather a "come down"?

This generation of mathematical teachers has done so much strenuous work in the way of reorganising mathematical instruction that there is no need to despair of its being able to elaborate a curriculum which shall leave in the minds of the pupils something even nobler than "the ambiguous case."

Let us think how this final review, closing the elementary course, might be conducted for the more intelligent pupils. Partly no doubt it requires a general oversight of the whole work done, considered without undue detail so as to emphasise the general ideas used, and their possibilities of importance when subjected to further study. Also the analytical and geometrical ideas find immediate application in the physical laboratory where a course of simple experimental mechanics should have been worked through. Here the point of view is twofold, the physical ideas and the mathematical ideas illustrate each other.

The mathematical ideas are essential to the precise formulation of the mechanical laws. The idea of a precise law of nature, the extent to which such laws are in fact verified in our experience, and the rôle of abstract thought in their formulation, then become practically apparent to the pupil. The whole topic of course requires detailed development with full particular illustration, and is not suggested as requiring merely a few bare abstract statements.

It would, however, be a grave error to put too much emphasis on the mere process of direct explanation of the previous work by way of final review. My point is, that the latter end of the course should be so selected that in fact the general ideas underlying all the previous mathematical work should be brought into prominence. This may well be done by apparently entering on a new subject. For example, the ideas of quantity and the ideas of number are fundamental to all precise thought. In the previous stages

they will not have been sharply separated; and children are, rightly enough, pushed on to algebra without too much bother and quantity. But the more intelligent among them at the end of their curriculum would gain immensely by a careful consideration of those fundamental properties of quantity in general which lead to the introduction of numerical measurement. This is a topic which also has the advantage that the necessary books are actually to hand. Euclid's fifth book is regarded by those qualified to judge as one of the triumphs of Greek mathematics. It deals with this very point. Nothing can be more characteristic of the hopelessly illiberal character of the traditional mathematical education than the fact that this book has always been omitted. It deals with ideas, and therefore was ostracised. Of course a careful selection of the more important propositions and a careful revision of the argument are required. This also is to hand in the publications of my immediate predecessor in the office of president, Prof. Hill. Furthermore, in Sir T. L. Heath's complete edition of Euclid, there is a full commentary embodying most of what has been said and thought on the point. Thus it is perfectly easy for teachers to inform themselves generally on the topic. The whole book would not be wanted, but just the few propositions which embody the fundamental ideas. The subject is not fit for backward pupils; but certainly it could be made interesting to the more advanced class. There would be great scope for interesting discussion as to the nature of quantity, and the tests which we should apply to ascertain when we are dealing with quantities. The work would not be at all in the air, but would be illustrated at every stage by reference to actual examples of cases where the quantitative character is absent, or obscure, or doubtful, or evident. Temperature, heat, electricity, pleasure and pain, mass and distance could all be considered.

Another idea which requires illustration is that of functionality. A function in analysis is the counterpart of a law in the physical universe, and of a curve in geometry. Children have studied the relations of functions to curves from the first beginning of their study of algebra, namely in drawing graphs. Of recent years there has been a great reform in respect to graphs. But at its present stage it has either gone too far or not far enough. It is not enough merely to draw a graph. The idea behind the graph--like the man behind the gun--is essential in order to make it effective. At present there is some tendency merely to set the children to draw curves, and there to leave the whole question.

In the study of simple algebraic functions and of trigonometrical functions we are initiating the study of the precise expression of physical laws. Curves are another way of representing these laws. The simple fundamental laws--such as the inverse square and the direct distance--should be passed under review, and the applications of the simple functions to express important concrete cases of physical laws considered. I cannot help thinking that the final review of this topic might well take the form of a study of some of the main ideas of the differential calculus applied to simple curves. There is nothing particularly difficult about the conception of a rate of change; and the differentiation of a few powers of _x_, such as _x_^2, _x_^3, etc., could easily be effected; perhaps by the aid of geometry even sin _x_ and cos _x_ could be differentiated. If we once abandon our fatal habit of cramming the children with theorems which they do not understand, and will never use, there will be plenty of time to concentrate their attention on really important topics. We can give them familiarity with conceptions which really influence thought.

Before leaving this topic of physical laws and mathematical functions, there are other points to be noticed. The fact that the precise law is never really verified by observation in its full precision is capable of easy illustration and of affording excellent examples. Again, statistical laws, namely laws which are only satisfied on the average by large numbers, can easily be studied and illustrated. In fact a slight study of statistical methods and their application to social phenomena affords one of the simplest examples of the application of algebraic ideas.

Another way in which the students' ideas can be generalised is by the use of the History of Mathematics, conceived not as a mere assemblage of the dates and names of men, but as an exposition of the general current of thought which occasioned the subjects to be objects of interest at the time of their first elaboration. The use of the History of Mathematics is to be considered at a later stage of our proceedings this afternoon. Accordingly I merely draw attention to it now, to point out that perhaps it is the very subject which may best obtain the results for which I am pleading.

We have indicated two main topics, namely general ideas of quantity and of laws of nature, which should be an object of study in the mathematical curriculum of a liberal education. But there is another side to mathematics which must not be overlooked. It is the chief instrument for discipline in logical method.

Now, what is logical method, and how can any one be trained in it?

Logical method is more than the mere knowledge of valid types of reasoning and practice in the concentration of mind necessary to follow them. If it were only this, it would still be very important; for the human mind was not evolved in the bygone ages for the sake of reasoning, but merely to enable mankind with more art to hunt between meals for fresh food supplies. Accordingly few people

can follow close reasoning without considerable practice.

More than this is wanted to make a good reasoner, or even to enlighten ordinary people with knowledge of what constitutes the essence of the art. The art of reasoning consists in getting hold of the subject at the right end, of seizing on the few general ideas which illuminate the whole, and of persistently marshalling all subsidiary facts round them. Nobody can be a good reasoner unless by constant practice he has realised the importance of getting hold of the big ideas and of hanging on to them like grim death. For this sort of training geometry is, I think, better than algebra. The field of thought of algebra is rather obscure, whereas space is an obvious insistent thing evident to all. Then the process of simplification, or abstraction, by which all irrelevant properties of matter, such as colour, taste, and weight, are put aside is an education in itself. Again, the definitions and the propositions assumed without proof illustrate the necessity of forming clear notions of the fundamental facts of the subject-matter and of the relations between them. All this belongs to the mere prolegomena of the subject. When we come to its development, its excellence increases. The learner is not initially confronted with any symbolism which bothers the memory by its rules, however simple they may be. Also, from the very beginning the reasoning, if properly conducted, is dominated by well-marked ideas which guide each stage of development. Accordingly the essence of logical method receives immediate exemplification.

Let us now put aside for the moment the limitations introduced by the dullness of average pupils and the pressure on time due to other subjects, and consider what geometry has to offer in the way of a liberal education. I will indicate some stages in the subject, without meaning that necessarily they are to be studied in this exclusive order. The first stage is the study of _congruence_. Our perception of congruence is in practice dependent on our judgments of the invariability of the intrinsic properties of bodies when their external circumstances are varying. But however it arises, congruence is in essence the correlation of two regions of space, point by point, so that all homologous distances and all homologous angles are equal. It is to be noticed that the definition of the equality of lengths and angles is their congruence, and all tests of equality, such as the use of the yard measure, are merely devices for making immediate judgments of congruence easy. I make these remarks to suggest that apart from the reasoning connected with it, congruence, both as an example of a larger and very far-reaching idea and also for its own sake, is well worthy of attentive consideration. The propositions concerning it elucidate the elementary properties of the triangle, the parallelogram, and the circle, and of the relations of two planes to each other. It is very desirable to restrict the proved propositions of this part within the narrowest bounds, partly by assuming redundant axiomatic propositions, and partly by introducing only those propositions of absolutely fundamental importance.

The second stage is the study of similarity. This can be reduced to three or four fundamental propositions. Similarity is an enlargement of the idea of congruence, and, like that idea, is another example of a one-to-one correlation of points of spaces. Any extension of study of this subject might well be in the direction of the investigation of one or two simple properties of similar and similarly situated rectilinear figures. The whole subject receives its immediate applications in plans and maps. It is important, however, to remember that trigonometry is really the method by which the main theorems are made available for use.

The third stage is the study of the elements of trigonometry. This is the study of the periodicity introduced by rotation and of properties preserved in a correlation of similar figures. Here for the first time we introduce a slight use of the algebraic analysis founded on the study of number and quantity. The importance of the periodic character of the functions requires full illustration. The simplest properties of the functions are the only ones required for the solution of triangles, and the consequent applications to surveying. The wealth of formulæ, often important in themselves, but entirely useless for this type of study, which crowd our books should be rigorously excluded, except so far as they are capable of being proved by the pupils as direct examples of the bookwork.

This question of the exclusion of formulæ is best illustrated by considering this example of Trigonometry, though of course I may well have hit on an unfortunate case in which my judgment is at fault. A great part of the educational advantage of the subject can be obtained by confining study to Trigonometry of one angle and by exclusion of the addition formulæ for the sine and cosine of the sum of two angles. The functions can be graphed, and the solution of triangles effected. Thus the aspects of the science as (1) embodying analytically the immediate results of some of the theorems deduced from congruence and similarity, (2) as a solution of the main problem of surveying, (3) as a study of the fundamental functions required to express periodicity and wave motion, will all be impressed on the pupils' minds both by bookwork and example.

If it be desired to extend this course, the addition formulæ should be added. But great care should be taken to exclude specialising the pupils in the wealth of formulæ which comes in their train. By "exclude" is meant that the pupils should not have spent time or energy in acquiring any facility in their deduction. The teacher may find it interesting to work a few such examples before a class. But such results are not among those which learners need retain. Also, I would exclude the whole subject of circumscribed and

inscribed circles both from Trigonometry and from the previous geometrical courses. It is all very pretty, but I do not understand what its function is in an elementary non-professional curriculum.

Accordingly, the actual bookwork of the subject is reduced to very manageable proportions. I was told the other day of an American college where the students are expected to know by heart ninety formulæ or results in Trigonometry alone. We are not quite so bad as that. In fact, in Trigonometry we have nearly approached the ideal here sketched out as far as our elementary courses are concerned.

The fourth stage introduces Analytical Geometry. The study of graphs in algebra has already employed the fundamental notions, and all that is now required is a rigorously pruned course on the straight line, the circle, and the three types of conic sections, defined by the forms of their equations. At this point there are two remarks to be made. It is often desirable to give our pupils mathematical information which we do not prove. For example, in co-ordinate geometry, the reduction of the general equation of the second degree is probably beyond the capacities of most of the type of students whom we are considering. But that need not prevent us from explaining the fundamental position of conics, as exhausting the possible types of such curves.

The second remark is to advocate the entire sweeping away of geometrical conics as a separate subject. Naturally, on suitable occasions the analysis of analytical geometry will be lightened by the use of direct deduction from some simple figure. But geometrical conics, as developed from the definition of a conic section by the focus and directrix property, suffers from glaring defects. It is hopelessly recondite. The fundamental definition of a conic, _SP_ = _e_ · _PM_, usual in this subject at this stage, is thoroughly bad. It is very recondite, and has no obvious importance. Why should such curves be studied at all, any more than those defined by an indefinite number of other formulæ? But when we have commenced the study of the Cartesian methods, the equations of the first and second degrees are naturally the first things to think about.

In this ideal course of Geometry, the fifth stage is occupied with the elements of Projective Geometry. The general ideas of cross ratio and of projection are here fundamental. Projection is yet a more general instance of that one-to-one correlation which we have already considered under congruence and similarity. Here again we must avoid the danger of being led into a bewildering wealth of detail.

The intellectual idea which projective geometry is to illustrate is the importance in reasoning of the correlation of all cases which can be proved to possess in common certain identical properties. The preservation of the projective properties in projection is the one important educational idea of the subject. Cross ratio only enters as the fundamental metrical property which is preserved. The few propositions considered are selected to illustrate the two allied processes which are made possible by this procedure. One is proof by simplification. Here the simplification is psychological and not logical--for the general case is logically the simplest. What is meant is: Proof by considering the case which is in fact the most familiar to us, or the easiest to think about. The other procedure is the deduction of particular cases from known general truths, as soon as we have a means of discovering such cases or a criterion for testing them.

The projective definition of conic sections and the identity of the results obtained with the curves derived from the general equation of the second degree are capable of simple exposition, but lie on the border-line of the subject. It is the sort of topic on which information can be given, and the proofs suppressed.

The course of geometry as here conceived in its complete ideal--and ideals can never be realised--is not a long one. The actual amount of mathematical deduction at each stage in the form of bookwork is very slight. But much more explanation would be given, the importance of each proposition being illustrated by examples, either worked out or for students to work, so selected as to indicate the fields of thought to which it applies. By such a course the student would gain an analysis of the leading properties of space, and of the chief methods by which they are investigated.

The study of the elements of mathematics, conceived in this spirit, would constitute a training in logical method together with an acquisition of the precise ideas which lie at the base of the scientific and philosophical investigations of the universe. Would it be easy to continue the excellent reforms in mathematical instruction which this generation has already achieved, so as to include in the curriculum this wider and more philosophic spirit? Frankly, I think that this result would be very hard to achieve as the result of single individual efforts. For reasons which I have already briefly indicated, all reforms in education are very difficult to effect. But the continued pressure of combined effort, provided that the ideal is really present in the minds of the mass of teachers, can do much, and effects in the end surprising modification. Gradually the requisite books get written, still more gradually the examinations are reformed so as to give weight to the less technical aspects of the subject, and then all recent experience has shown that the

majority of teachers are only too ready to welcome any practicable means of rescuing the subject from the reproach of being a mechanical discipline.

CHAPTER V

THE PRINCIPLES OF MATHEMATICS IN RELATION TO ELEMENTARY TEACHING

(_International Congress of Mathematicians, Cambridge, August, 1912_)

WE are concerned not with the advanced teaching of a few specialist mathematical students, but with the mathematical education of the majority of boys in our secondary schools. Again these boys must be divided into two sections: one section consists of those who desire to restrict their mathematical education; the other section is made up of those who will require some mathematical training for their subsequent professional careers, either in the form of definite mathematical results or in the form of mathematically trained minds.

I shall call the latter of these two sections the mathematical section, and the former the non-mathematical section. But I must repeat that by the mathematical section is meant that large number of boys who desire to learn more than the minimum amount of mathematics. Furthermore, most of my remarks about these sections of boys apply also to elementary classes of our University students.

The subject of this paper is the investigation of the place which should be occupied by modern investigations respecting mathematical principles in the education of both of these sections of school-boys.

To find a foothold from which to start the inquiry, let us ask why the non-mathematical section should be taught any mathematics at all beyond the barest elements of arithmetic. What are the qualities of mind which a mathematical training is designed to produce when it is employed as an element in a liberal education?

My answer, which applies equally to both sections of students, is that there are two allied forms of mental discipline which should be acquired by a well-designed mathematical course. These two forms though closely allied are perfectly distinct.

The first form of discipline is not in its essence logical at all. It is the power of clearly grasping abstract ideas, and of relating them to particular circumstances. In other words, the first use of mathematics is to strengthen the power of abstract thought. I repeat that in its essence this has nothing to do with logic, though as a matter of fact a logical discipline is the best method of producing the desired effect. It is not the philosophical theory of abstract ideas which is to be acquired, but the habit and the power of using them. There is one and only way of acquiring the habit and the power of using anything, that is by the simple common-place method of habitually using it. There is no other short cut. If in education we desire to produce a certain conformation of mind, we must day by day, and year by year, accustom the students' minds to grow into the desired structural shape. Thus to teach the power of grasping abstract ideas and the habit of using them, we must select a group of such ideas, which are important and are also easy to think about because they are clear and definite.

The fundamental mathematical truths concerning geometry, ratio, quantity, and number, satisfy these conditions as do no others. Hence, the fundamental universal position held by mathematics as an element of a liberal education.

But what are the fundamental mathematical truths concerning geometry, quantity and number?

At this point we come to the great question of the relation between the modern science of the principles of mathematics and a mathematical education.

My answer to the question as to these fundamental mathematical truths is, that in any absolute sense there are none. There is no unique small body of independent primitive unproved propositions which are the necessary starting points of all mathematical reasoning on these subjects. In mathematical reasoning the only absolute necessary pre-suppositions are those which make logical deduction possible. Between these absolute logical truths and so-called fundamental truths concerning geometry, quantity and number, there is a whole new world of mathematical subjects concerning the logic of propositions, of classes, and of relations.

But this subject is too abstract to form an elementary training ground in the difficult art of abstract thought.

It is for this reason that we have to make a compromise and start from such obvious general ideas as naturally occur to all men when they perceive objects with their senses.

In geometry, the ideas elaborated by the Greeks and presented by Euclid are, roughly speaking, those adapted for our purpose, namely, ideas of volumes, surfaces, lines, of straightness and of curvature, of intersection and of congruence, of greater and less, of similarity, shape, and scale. In fact, we use in education those general ideas of spatial properties which must be habitually present in the mind of any one who is to observe the world of phenomena with understanding.

Thus we come back to Plato's opinion that for a liberal education, geometry, as he knew it, is the queen of sciences.

In addition to geometry, there remain the ideas of quantity, ratio, and of number. This in practice means, elementary algebra. Here the prominent ideas are those of "any number," in other words, the use of the familiar _x_, _y_, _z_, and of the dependence of variables on each other, or otherwise, the idea of functionality. All this is to be gradually acquired by the continual use of the very simplest functions which we can devise: of linear functions, graphically represented by straight lines; of quadratic functions, graphically represented by parabolas; and of those simple implicit functions, graphically represented by conic sections. Thence, with good fortune and a willing class, we can advance to the ideas of rates of increase, still confining ourselves to the simplest possible cases.

I wish here emphatically to remind you that both in geometry and in algebra a clear grasp of these general ideas is not what the pupil starts from, it is the goal at which he is to arrive. The method of progression is continual practice in the consideration of the simplest particular cases, and the goal is not philosophical analysis but the power of use.

But how is he to practise himself in their use? He cannot simply sit down and think of the relation _y_ = _x_ + 1, he must employ it in some simple obvious way.

This brings us to the second power of mind which is to be produced by a mathematical training, namely, the power of logical reasoning. Here again, it is not the knowledge of the philosophy of logic which it is essential to teach, but the habit of thinking logically. By logic, I mean deductive logic.

Deductive logic is the science of certain relations, such as implication, etc., between general ideas. When logic begins, definite particular individual things have been banished. I cannot relate logically this thing to that thing, for example this pen to that pen, except by the indirect way of relating some general idea which applies to this pen to some general idea which applies to that pen. And the individualities of the two pens are quite irrelevant to the logical process. This process is entirely concerned with the two general ideas. Thus the practice of logic is a certain way of employing the mind in the consideration of such ideas; and an elementary mathematical training is in fact nothing else but the logical use of the general ideas respecting geometry and algebra which we have enumerated above. It has therefore, as I started this paper by stating, a double advantage. It makes the mind capable of abstract thought, and it achieves this object by training the mind in the most important kind of abstract thought, namely, deductive logic.

I may remind you that other choices of a type of abstract thought might be made. We might train the children to contemplate directly the beauty of abstract moral ideas, in the hope of making them religious mystics. The general practice of education has decided in favour of logic, as exemplified in elementary mathematics.

We have now to answer the further question, what is the rôle of logical precision in the teaching of mathematics? Our general answer to the implied question is obvious: logical precision is one of the two objects of the teaching of mathematics, and it is the only weapon by which the teaching of mathematics can achieve its other object. To teach mathematics is to teach logical precision. A mathematical teacher who has not taught that has taught nothing.

But having stated this thesis in this unqualified way, its meaning must be carefully explained; for otherwise its real bearing on the problem will be entirely misunderstood.

Logical precision is the faculty to be acquired. It is the quality of mind which it is the object of the teaching to impart. Thus the habit of reading great literature is the goal at which a literary education aims. But we do not expect a child to start its first lesson by reading for itself Shakespeare. We recognise that reading is impossible till the pupil has learnt its alphabet and can spell, and then we start it with books of one syllable.

In the same way, a mathematical education should grow in logical precision. It is folly to expect the same careful logical analysis at the commencement of the training as would be appropriate at the end. It is an entire misconception of my thesis to construe it as meaning that a mathematical training should assume in the pupil a power of concentrated logical thought. My thesis is in fact the exact opposite, namely, that this power cannot be assumed, and has got to be acquired, and that a mathematical training is nothing else than the process of acquiring it. My whole groundwork of assumption is that this power does not initially exist in a fully developed state. Of course like every other power which is acquired, it must be developed gradually.

The various stages of development must be guided by the judgment and the genius of the teacher. But what is essential is, that the teacher should keep clearly in his mind that it is just this power of logical precise reasoning which is the whole object of his efforts. If his pupils have in any measure gained this, they have gained all.

We have not yet, however, fully considered this part of our subject. Logical precision is the full realisation of the steps of the argument. But what are the steps of the argument? The full statement of all the steps is far too elaborate and difficult an operation to be introduced into the mathematical reasoning of an educational curriculum. Such a statement involves the introduction of abstract logical ideas which are very difficult to grasp, because there is so rarely any need to make them explicit in ordinary thought. They are therefore not a fit subject-ground for an elementary education.

I do not think that it is possible to draw any theoretical line between those logical steps which form a theoretically full logical investigation, and those which are full enough for most practical purposes, including that of education. The question is one of psychology, to be solved by a process of experiment. The object to be attained is to gain that amount of logical alertness which will enable its possessors to detect fallacy and to know the types of sound logical deduction. The objects of going further are partly philosophical, and also partly to lay bare abstract ideas whose investigation is in itself important. But both these objects are foreign to education.

My opinion is, that, on the whole, the type of logical precision handed down to us by the Greek mathematicians is, roughly speaking, what we want. In geometry, this means the sort of precision which we find in Euclid. I do not mean that we should use his famous _Elements_ as a text-book, nor that here and there a certain compression in his mode of exposition is not advisable. All this is mere detail. What I do mean is, that the sort of logical transition which he made explicit, we should make explicit, and that the sort of transition which he omits, we should omit.

I doubt, however, whether it is desirable to plunge the student into the full rigour of euclidean geometry without some mitigation. It is for this reason that the modern habit, at least in England, of laying great stress in the initial stages on training the pupil in simple constructions from numerical data is to be praised. It means that after a slight amount of reasoning on the euclidean basis of accuracy, the mind of the learner is relieved by doing the things in various special cases, and noting by rough measurements that the desired results are actually attained. It is important, however, that the measurements be not mistaken for the proofs. Their object is to make the beginner apprehend what the abstract ideas really mean.

Again in algebra, the notation and the practical use of the symbols should be acquired in the simplest cases, and the more theoretical treatment of the symbolism reserved to a suitable later stage. My rule would be initially to learn the meaning of the ideas by a crude practice in simple ways, and to refine the logical procedure in preparation for an advance to greater generality. In fact the thesis of my paper can be put in another way thus, the object of a mathematical education is, to acquire the powers of analysis, of generalisation, and of reasoning. The two processes of analysis and generalisation were in my previous statement put together as the power of grasping abstract ideas.

But in order to analyse and to generalise, we must commence with the crude material of ideas which are to be analysed and generalised. Accordingly it is a positive error in education to start with the ultimate products of this process, namely the ideas in their refined analysed and generalised forms. We are thereby skipping an important part of the training, which is to take the ideas as they actually exist in the child's mind, and to exercise the child in the difficult art of civilising them and clothing them.

The schoolmaster is in fact a missionary, the savages are the ideas in the child's mind; and the missionary shirks his main task if he refuse to risk his body among the cannibals.

At this point I should like to turn your attention to those pupils forming the mathematical section. There is an idea, widely prevalent, that it is possible to teach mathematics of a relatively advanced type--such as differential calculus, for instance--in a way useful to physicists and engineers without any attention to its logic or its theory.

This seems to me to be a profound mistake. It implies that a merely mechanical knowledge without understanding of ways of arriving at mathematical results is useful in applied science. It is of no use whatever. The results themselves can all be found stated in the appropriate pocket books and in other elementary works of reference. No one when applying a result need bother himself as to why it is true. He accepts it and applies it. What is of supreme importance in physics and in engineering is a mathematically trained mind, and such a mind can only be acquired by a proper mathematical discipline.

I fully admit that the proper way to start such a subject as the differential calculus is to plunge quickly into the use of the notation in a few absurdly simple cases, with a crude explanation of the idea of rates of increase. The notation as thus known can then be used by the lecturers in the Physical and Engineering Laboratories. But the mathematical training of the applied scientists consists in making these ideas precise and the proofs accurate.

I hope that the thesis of this paper respecting the position of logical precision in the teaching of mathematics has been rendered plain. The habit of logical precision with its necessary concentration of thought upon abstract ideas is not wholly possible in the initial stages of learning. It is the ideal at which the teacher should aim. Also logical precision, in the sense of logical explicitness, is not an absolute thing: it is an affair of more or less. Accordingly the quantity of explicitness to be introduced at each stage of progress must depend upon the practical judgment of the teacher. Lastly, in a sense, the instructed mind is less explicit; for it travels more quickly over a well-remembered path, and may save the trouble of putting into words trains of thought which are very obvious to it. But on the other hand it atones for this rapidity by a concentration on every subtle point where a fallacy can lurk. The habit of logical precision is the instinct for the subtle difficulty.

CHAPTER VI

THE ORGANISATION OF THOUGHT

(_Presidential Address to Section A, British Association, Newcastle, 1916_)

THE subject of this address is the organisation of thought, a topic evidently capable of many diverse modes of treatment. I intend more particularly to give some account of that department of logical science with which some of my own studies have been connected. But I am anxious, if I can succeed in so doing, to handle this account so as to exhibit the relation with certain considerations which underlie general scientific activities.

It is no accident that an age of science has developed into an age of organisation. Organised thought is the basis of organised action. Organisation is the adjustment of diverse elements so that their mutual relations may exhibit some predetermined quality. An epic poem is a triumph of organisation, that is to say, it is a triumph in the unlikely event of its being a good epic poem. It is the successful organisation of multitudinous sounds of words, associations of words, pictorial memories of diverse events and feelings ordinarily occurring in life, combined with a special narrative of great events: the whole so disposed as to excite emotions which, as defined by Milton, are simple, sensuous, and passionate. The number of successful epic poems is commensurate, or rather, is inversely commensurate, with the obvious difficulty of the task of organisation.

Science is the organisation of thought. But the example of the epic poem warns us that science is not any organisation of thought. It is an organisation of a certain definite type which we will endeavour to determine.

Science is a river with two sources, the practical source and the theoretical source. The practical source is the desire to direct our actions to achieve predetermined ends. For example, the British nation, fighting for justice, turns to science, which teaches it the importance of compounds of nitrogen. The theoretical source is the desire to understand. Now I am going to emphasise the importance of theory in science. But to avoid misconception I most emphatically state that I do not consider one source as in any sense nobler than the other, or intrinsically more interesting. I cannot see why it is nobler to strive to understand than to busy oneself with the right ordering of one's actions. Both have their bad sides; there are evil ends directing actions, and there are ignoble curiosities of the understanding.

The importance, even in practice, of the theoretical side of science arises from the fact that action must be immediate, and takes place under circumstances which are excessively complicated. If we wait for the necessities of action before we commence to arrange our ideas, in peace we shall have lost our trade, and in war we shall have lost the battle. Success in practice depends on theorists who, led by other motives of exploration, have been there before, and by some good chance have hit upon the relevant ideas. By a theorist I do not mean a man who is up in the clouds, but a man whose motive for thought is the desire to formulate

correctly the rules according to which events occur. A successful theorist should be excessively interested in immediate events, otherwise he is not at all likely to formulate correctly anything about them. Of course, both sources of science exist in all men.

Now, what is this thought organisation which we call science? The first aspect of modern science which struck thoughtful observers was its inductive character. The nature of induction, its importance, and the rules of inductive logic have been considered by a long series of thinkers, especially English thinkers: Bacon, Herschel, J. S. Mill, Venn, Jevons, and others. I am not going to plunge into an analysis of the process of induction. Induction is the machinery and not the product, and it is the product which I want to consider. When we understand the product we shall be in a stronger position to improve the machinery.

First, there is one point which it is necessary to emphasise. There is a tendency in analysing scientific processes to assume a given assemblage of concepts applying to nature, and to imagine that the discovery of laws of nature consists in selecting by means of inductive logic some one out of a definite set of possible alternative relations which may hold between the things in nature answering to these obvious concepts. In a sense this assumption is fairly correct, especially in regard to the earlier stages of science. Mankind found itself in possession of certain concepts respecting nature--for example, the concept of fairly permanent material bodies--and proceeded to determine laws which related the corresponding percepts in nature. But the formulation of laws changed the concepts, sometimes gently by an added precision, sometimes violently. At first this process was not much noticed, or at least was felt to be a process curbed within narrow bounds, not touching fundamental ideas. At the stage where we now are, the formulation of the concepts can be seen to be as important as the formulation of the empirical laws connecting the events in the universe as thus conceived by us. For example, the concepts of life, of heredity, of a material body, of a molecule, of an atom, of an electron, of energy, of space, of time, of quantity, and of number. I am not dogmatising about the best way of getting such ideas straight. Certainly it will only be done by those who have devoted themselves to a special study of the facts in question. Success is never absolute, and progress in the right direction is the result of a slow, gradual process of continual comparison of ideas with facts. The criterion of success is that we should be able to formulate empirical laws, that is, statements of relations, connecting the various parts of the universe as thus conceived, laws with the property that we can interpret the actual events of our lives as being our fragmentary knowledge of this conceived interrelated whole.

But, for the purpose of science, what is the actual world? Has science to wait for the termination of the metaphysical debate till it can determine its own subject-matter? I suggest that science has a much more homely starting-ground. Its task is the discovery of the relations which exist within that flux of perceptions, sensations, and emotions which forms our experience of life. The panorama yielded by sight, sound, taste, smell, touch, and by more inchoate sensible feelings, is the sole field of activity. It is in this way that science is the thought organisation of experience. The most obvious aspect of this field of actual experience is its disorderly character. It is for each person a _continuum_, fragmentary, and with elements not clearly differentiated. The comparison of the sensible experiences of diverse people brings its own difficulties. I insist on the radically untidy, ill-adjusted character of the fields of actual experience from which science starts. To grasp this fundamental truth is the first step in wisdom, when constructing a philosophy of science. This fact is concealed by the influence of language, moulded by science, which foists on us exact concepts as though they represented the immediate deliverances of experience. The result is, that we imagine that we have immediate experience of a world of perfectly defined objects implicated in perfectly defined events which, as known to us by the direct deliverance of our senses, happen at exact instants of time, in a space formed by exact points, without parts and without magnitude: the neat, trim, tidy, exact world which is the goal of scientific thought.

My contention is, that this world is a world of ideas, and that its internal relations are relations between abstract concepts, and that the elucidation of the precise connection between this world and the feelings of actual experience is the fundamental question of scientific philosophy. The question which I am inviting you to consider is this: How does exact thought apply to the fragmentary, vague _continua_ of experience? I am not saying that it does not apply: quite the contrary. But I want to know how it applies. The solution I am asking for is not a phrase, however brilliant, but a solid branch of science, constructed with slow patience, showing in detail how the correspondence is effected.

The first great steps in the organisation of thought were due exclusively to the practical source of scientific activity, without any admixture of theoretical impulse. Their slow accomplishment was the cause and also the effect of the gradual evolution of moderately rational beings. I mean the formation of the concepts of definite material objects, of the determinate lapse of time, of simultaneity, of recurrence, of definite relative position, and of analogous fundamental ideas, according to which the flux of our experience is mentally arranged for handy reference: in fact, the whole apparatus of commonsense thought. Consider in your mind some definite chair. The concept of that chair is simply the concept of all the interrelated experiences connected with that chair--namely, of the experience of the folk who made it, of the folk who sold it, of the folk who have seen it or used it, of the man

who is now experiencing a comfortable sense of support, combined with our expectations of an analogous future, terminated finally by a different set of experiences when the chair collapses and becomes firewood. The formation of that type of concept was a tremendous job, and zoologists and geologists tell us that it took many tens of millions of years. I can well believe it.

I now emphasise two points. In the first place, science is rooted in what I have just called the whole apparatus of commonsense thought. That is the _datum_ from which it starts, and to which it must recur. We may speculate, if it amuses us, of other beings in other planets who have arranged analogous experiences according to an entirely different conceptual code--namely, who have directed their chief attention to different relations between their various experiences. But the task is too complex, too gigantic, to be revised in its main outlines. You may polish up commonsense, you may contradict it in detail, you may surprise it. But ultimately your whole task is to satisfy it.

In the second place, neither commonsense nor science can proceed with their task of thought organisation without departing in some respect from the strict consideration of what is actual in experience. Think again of the chair. Among the experiences upon which its concept is based, I included our expectations of its future history. I should have gone further and included our imagination of all the possible experiences which in ordinary language we should call perceptions of the chair which might have occurred. This is a difficult question, and I do not see my way through it. But, at present, in the construction of a theory of space and of time there seem insuperable difficulties if we refuse to admit ideal experiences.

This imaginative perception of experiences, which, if they occurred, would be coherent with our actual experiences, seems fundamental in our lives. It is neither wholly arbitrary, nor yet fully determined. It is a vague background which is only made in part definite by isolated activities of thought. Consider, for example, our thoughts of the unseen flora of Brazil.

Ideal experiences are closely connected with our imaginative reproduction of the actual experiences of other people, and also with our almost inevitable conception of ourselves as receiving our impressions from an external complex reality beyond ourselves. It may be that an adequate analysis of every source and every type of experience yields demonstrative proof of such a reality and of its nature. Indeed, it is hardly to be doubted that this is the case. The precise elucidation of this question is the problem of metaphysics. One of the points which I am urging in this address is, that the basis of science does not depend on the assumption of any of the conclusions of metaphysics; but that both science and metaphysics start from the same given groundwork of immediate experience, and in the main proceed in opposite directions on their diverse tasks.

For example, metaphysics inquires how our perceptions of the chair relate us to some true reality. Science gathers up these perceptions into a determinate class, adds to them ideal perceptions of analogous sort, which under assignable circumstances would be obtained, and this single concept of that set of perceptions is all that science needs; unless indeed you prefer that thought find its origin in some legend of those great twin brethren, the Cock and Bull.

My immediate problem is to inquire into the nature of the texture of science. Science is essentially logical. The nexus between its concepts is a logical nexus, and the grounds for its detailed assertions are logical grounds. King James said, "No bishops, no king." With greater confidence we can say, "No logic, no science." The reason for the instinctive dislike which most men of science feel towards the recognition of this truth is, I think, the barren failure of logical theory during the past three or four centuries. We may trace this failure back to the worship of authority, which in some respects increased in the learned world at the time of the Renaissance. Mankind then changed its authority, and this fact temporally acted as an emancipation. But the main fact, and we can find complaints[2] of it at the very commencement of the modern movement, was the establishment of a reverential attitude towards any statement made by a classical author. Scholars became commentators on truths too fragile to bear translation. A science which hesitates to forget its founders is lost. To this hesitation I ascribe the barrenness of logic. Another reason for distrust of logical theory and of mathematics is the belief that deductive reasoning can give you nothing new. Your conclusions are contained in your premises, which by hypothesis are known to you.

In the first place this last condemnation of logic neglects the fragmentary, disconnected character of human knowledge. To know one premise on Monday, and another premise on Tuesday, is useless to you on Wednesday. Science is a permanent record of premises, deductions, and conclusions, verified all along the line by its correspondence with facts. Secondly, it is untrue that when we know the premises we also know the conclusions. In arithmetic, for example, mankind are not calculating boys. Any theory which proves that they are conversant with the consequences of their assumptions must be wrong. We can imagine beings who possess such insight. But we are not such creatures. Both these answers are, I think, true and relevant. But they are not satisfactory. They are too much in the nature of bludgeons, too external. We want something more explanatory of the very real

difficulty which the question suggests. In fact, the true answer is embedded in the discussion of our main problem of the relation of logic to natural science.

It will be necessary to sketch in broad outline some relevant features of modern logic. In doing so I shall try to avoid the profound general discussions and the minute technical classifications which occupy the main part of traditional logic. It is characteristic of a science in its earlier stages--and logic has become fossilised in such a stage--to be both ambitiously profound in its aims and trivial in its handling of details.

We can discern four departments of logical theory. By an analogy which is not so very remote I will call these departments or sections the arithmetic section, the algebraic section, the section of general-function theory, the analytical section. I do not mean that arithmetic arises in the first section, algebra in the second section, and so on; but the names are suggestive of certain qualities of thought in each section which are reminiscent of analogous qualities in arithmetic, in algebra, in the general theory of a mathematical function, and in the mathematical analysis of the properties of particular functions.

The first section--namely, the arithmetic stage--deals with the relations of definite propositions to each other, just as arithmetic deals with definite numbers. Consider any definite proposition; call it "_p_." We conceive that there is always another proposition which is the direct contradictory to "_p_"; call it "not-_p_." When we have got two propositions, _p_ and _q_, we can form derivative propositions from them, and from their contradictories. We can say, "At last one of _p_ or _q_ is true, and perhaps both." Let us call this proposition "_p_ or _q_." I may mention as an aside that one of the greatest living philosophers has stated that this use of the word "or"--namely, "_p_ or _q_" in the sense that either or both may be true--makes him despair of exact expression. We must brave his wrath, which is unintelligible to me.

We have thus got hold of four new propositions, namely, "_p_ or _q_," and "not-_p_ or _q_," and "_p_ or not-_q_," and "not-_p_ or not-_q_." Call these the set of disjunctive derivatives. There are, so far, in all eight propositions, _p_, not-_p_, _q_, not-_q_, and the four disjunctive derivatives. Any pair of these eight propositions can be taken, and substituted for _p_ and _q_ in the foregoing treatment. Thus each pair yields eight propositions, some of which may have been obtained before. By proceeding in this way we arrive at an unending set of propositions of growing complexity, ultimately derived from the two original propositions _p_ or _q_. Of course, only a few are important. Similarly we can start from three propositions, _p_, _q_, _r_, or from four propositions, _p_, _q_, _r_, _s_, and so on. Any one of the propositions of these aggregates may be true or false. It has no other alternative. Whichever it is, true or false, call it the "truth-value" of the proposition.

The first section of logical inquiry is to settle what we know of the truth-values of these propositions, when we know the truth-values of some of them. The inquiry, so far as it is worth while carrying it, is not very abstruse, and the best way of expressing its results is a detail which I will not now consider. This inquiry forms the arithmetic stage.

The next section of logic is the algebraic stage. Now, the difference between arithmetic and algebra is, that in arithmetic definite numbers are considered, and in algebra symbols--namely, letters--are introduced which stand for any numbers. The idea of a number is also enlarged. These letters, standing for any numbers, are called sometimes variables and sometimes parameters. Their essential characteristic is that they are undetermined, unless, indeed, the algebraic conditions which they satisfy implicitly determine them. Then they are sometimes called unknowns. An algebraic formula with letters is a blank form. It becomes a determinate arithmetic statement when definite numbers are substituted for the letters. The importance of algebra is a tribute to the study of form. Consider now the following proposition--

The specific heat of mercury is 0·033.

This is a definite proposition which, with certain limitations, is true. But the truth-value of the proposition does not immediately concern us. Instead of mercury put a mere letter which is the name of some undetermined thing: we get--

The specific heat of _x_ is 0·033.

This is not a proposition; it has been called by Russell a propositional function. It is the logical analogy of an algebraic expression. Let us write $f(_x_)$ for any propositional function.

We could also generalise still further, and say,

The specific heat of _x_ is _y_.

We thus get another propositional function, F(_x_, _y_), of two arguments _x_ and _y_, and so on for any number of arguments.

Now, consider $f(_x_)$. There is the range of values of _x_, for which $f(_x_)$ is a proposition, true or false. For values of _x_ outside this range, $f(_x_)$ is not a proposition at all, and is neither true nor false. It may have vague suggestions for us, but it has no unit meaning of definite assertion. For example,

The specific heat of water is 0·033

is a proposition which is false; and--

The specific heat of virtue is 0·033

is, I should imagine, not a proposition at all; so that it is neither true nor false, though its component parts raise various associations in our minds. This range of values, for which $f(_x_)$ has sense, is called the "type" of the argument _x_.

But there is also a range of values of _x_ for which $f(_x_)$ is a true proposition. This is the class of those values of the argument which _satisfy_ $f(_x_)$. This class may have no members, or, in the other extreme, the class may be the whole type of the arguments.

We thus conceive two general propositions respecting the indefinite number of propositions which share in the same logical form, that is, which are values of the same propositional function. One of these propositions is,

$f(_x_)$ yields a true proposition for each value of _x_ of the proper type;

the other proposition is,

There is a value of _x_ for which $f(_x_)$ is true.

Given two, or more, propositional functions $f(_x_)$ and $\varphi(_x_)$ with the same argument _x_, we form derivative propositional functions, namely,

$f(_x_)$ or $\varphi(_x_)$, $f(_x_)$ or not-$\varphi(_x_)$,

and so on with the contradictories, obtaining, as in the arithmetical stage, an unending aggregate of propositional functions. Also each propositional function yields two general propositions. The theory of the interconnection between the truth-values of the general propositions arising from any such aggregate of propositional functions forms a simple and elegant chapter of mathematical logic.

In this algebraic section of logic the theory of types crops up, as we have already noted. It cannot be neglected without the introduction of error. Its theory has to be settled at least by some safe hypothesis, even if it does not go to the philosophic basis of the question. This part of the subject is obscure and difficult, and has not been finally elucidated, though Russell's brilliant work has opened out the subject.

The final impulse to modern logic comes from the independent discovery of the importance of the logic variable by Frege and Peano. Frege went further than Peano, but by an unfortunate symbolism rendered his work so obscure that no one fully recognised his meaning who had not found it out for himself. But the movement has a large history reaching back to Leibniz and even to Aristotle. Among English contributors are De Morgan, Boole, and Sir Alfred Kempe; their work is of the first rank.

The third logical section is the stage of general-function theory. In logical language, we perform in this stage the transition from intension to extension, and investigate the theory of denotation. Take the propositional function, $f(_x_)$. There is the class, or range of values for _x_, whose members satisfy $f(_x_)$. But the same range may be the class whose members satisfy another propositional function $\varphi(_x_)$. It is necessary to investigate how to indicate the class by a way which is indifferent as between the various propositional functions which are satisfied by any member of it, and of it only. What has to be done is to analyse the nature of propositions about a class--namely, those propositions whose truth-values depend on the class itself and not on the particular meaning by which the class is indicated.

Furthermore, there are propositions about alleged individuals indicated by descriptive phrases: for example, propositions about "the present King of England," who does exist, and "the present Emperor of Brazil," who does not exist. More complicated, but analogous, questions involving propositional functions of two variables involve the notion of "correlation," just as functions of one

argument involve classes. Similarly functions of three arguments yield three-cornered correlations, and so on. This logical section is one which Russell has made peculiarly his own by work which must always remain fundamental. I have called this the section of functional theory, because its ideas are essential to the construction of logical denoting functions which include as a special case ordinary mathematical functions, such as sine, logarithm, etc. In each of these three stages it will be necessary gradually to introduce an appropriate symbolism, if we are to pass on to the fourth stage.
